### Comment on "Nucleation of $^3\text{He-B}$ from the $A$ Phase: A Cosmic-Ray Effect?"

In an interesting Letter, Leggett<sup>1</sup> suggests that the nucleation of  $^3\text{He-B}$  from the metastable  $A$  phase is a consequence of the passage of a cosmic ray through the sample cell. Here we present new experimental data obtained with a rotating cryostat in NMR experiments<sup>2</sup> on  $^3\text{He}$ . Figure 1(a) shows our data, taken on the  $A \rightarrow B$  transition in magnetic fields of 28.4 and 56.9 mT; no field dependence was found between these values. We find that supercooling of the  $A$  phase into the  $B$  phase is substantial, and there appears to be a threshold temperature ("catastrophe line")  $T_{AB}^*(p) \ll T_{AB}(p)$ , where the metastable  $A$  phase first changes into  $^3\text{He-B}$ .

FIG. 1. (a) Supercooling of the  $A$  phase into the  $B$  phase as a function of pressure. (b) Observed nucleation events (histogram) at 29.3 bars are inconsistent with the probability distribution of Ref. 1 with  $P(T) \propto (1 - T/T_{AB}^*)^3$ . Clearly, only a much more sharply peaked probability at a lower temperature than suggested in Ref. 1 can describe the data; an exponential law for the activation process might be appropriate.

We want to emphasize that in our  $^3\text{He}$  cell the  $A \rightarrow B$  transition could *only* be observed *during cooling*, never on warmup. The cooling rate varied between 5 and 29  $\mu\text{K}/\text{min}$ , but no clear dependence of  $B$ -phase nucleation on the cooling rate could be established. When the temperature was stable, the  $A$  phase was found to persist, and no  $A \rightarrow B$  transition was ever observed in this case. For example, at  $p = 29.3$  bars (with  $T_{AB} = 0.85 T_c$ ) and 28.4 mT, the  $A$  liquid was cooled as low as  $T_{\min} = 0.67 T_c$ , and was maintained below  $0.7 T_c$  for 2 h; in this run the metastable  $A$  phase persisted a total of 8 h, never nucleating the  $B$  phase. The temperatures in Fig. 1 are upper-bound estimates for  $T_{AB}^*$ . They are determined from NMR susceptibility measurements on platinum powder immersed in the  $^3\text{He}$ . A comparison with the  $A$ -phase NMR frequency-shift measurement shows that on cooling, the platinum temperature lags behind, at a cooling rate of 20–30  $\mu\text{K}/\text{min}$  by  $\leq 0.02 T/T_c$ . Even lower liquid temperatures exist in the heat exchanger between the  $^3\text{He}$  sample and the refrigerator.

Figure 1(b) represents the data points at 29.3 bars as a histogram and compares them with a fitted distribution of nucleation probability. We conclude that experimentally the nucleation mechanism appears to be active only in a narrow temperature interval near the "catastrophe line" well below the thermodynamic  $A \rightarrow B$  transition. An interesting point to note is that on cooling through the  $A \rightarrow B$  transition during rotation, the  $A$  phase stayed supercooled as long as in the stationary liquid. This is further (indirect) evidence in support of the conclusion<sup>3</sup> that continuous vortices are induced by rotation in a bulk liquid sample of  $^3\text{He-A}$ .
