By means of high-resolution O K-edge and Cu L$_{23}$-edge x-ray absorption near-edge-structure spectroscopy continuous increase of the CuO$_2$-plane hole concentration with increasing Ca-substitution level has been established for the superconductive, oxygen-depleted ($z < 0$) (Pb$_{2/3}$Cu$_{1/3}$)$_3$Sr$_2$(Y$_{1-x}$Ca$_x$)Cu$_2$O$_{8+z}$ [(Pb$_{2/3}$Cu$_{1/3}$)$_3$-3212] phase with a three-layer PbO-Cu-PbO charge-reservoir block. For the O K-edge absorption, a pre-edge peak at $\sim$528.3 eV is seen, originating from the excitation of the O 1s electron to the O 2p hole state located in the CuO$_2$ plane. With increasing Ca-substitution level, the intensity of this peak continuously increases within the substitution range studied, i.e., $0 \leq x \leq 0.5$. Consistently, with increasing $x$, the shoulder on the high-energy side of the main absorption peak at $\sim$932.0 eV in the Cu L$_{23}$-edge spectra, i.e., a feature typically assigned to formally trivalent copper, enhances. From the Cu L$_{23}$-edge spectra it was furthermore confirmed that the charge-reservoir copper remains in the monovalent state, indicating that the holes created through Ca substitution are directed solely into the superconductive CuO$_2$ plane. In terms of increasing the CuO$_2$-plane hole concentration, Ca substitution was found to work more efficiently in (Pb$_{2/3}$Cu$_{1/3}$)$_3$-3212 as compared to, e.g., the related Bi-2212 phase.

I. INTRODUCTION

In the layered structures of superconductive copper oxides, $M_mA_2Q_{n-1}CuO_n+z_{2+2n\pm\delta} [M-m2(n-1)n]$, the superconductive block, CuO$_2$-(Q-CuO$_2$)$_{n-1}$ is sandwiched by AO layers and $M_mO_m$-z layers, “charge-reservoir” blocks forming a layer sequence, AO-CuO$_2$-(Q-CuO$_2$)$_{n-1}$-AO-(MO$_1$-$z$). Even though the CuO$_2$-plane hole concentration is known to crucially control the superconductivity characteristics, determination of the local hole concentration of individual CuO$_2$ planes and MO$_1$-$z$ layers, i.e., the distribution of holes among the different layers over the unit cell, has remained an unsolved problem for most of the known $M-m2(n-1)n$ phases. In the case of, e.g., Bi-, Pb-, Tl-, Hg- and Cu-m2(n-1)n superconductors, one of the uncertainties arises from the fact that, besides the CuO$_2$-plane Cu, also the charge-reservoir constituent $M$ is likely to possess a mixed-valence value. The x-ray absorption near-edge structure (XANES) technique provides us with a direct probe for investigating the local concentration of holes at the distinct copper and oxygen sites in superconductive copper-oxide phases. So far, XANES measurements—both O K-edge and Cu K- and L$_{23}$-edge studies—have been most intensively applied for establishing changes in site-specific hole concentrations of the Cu$A_2QCu_2O_{8+z}$ or Cu-1212 phase, i.e., the distribution of holes among the superconductive CuO$_2$ plane and the charge-reservoir CuO$_2$ chain, with varying cation-substitution level and/or oxygen content. Note that, Cu-1212 is nothing but the so-called “123” phase. Also note that in the present contribution “z” is used instead of “1$-$δ” for the amount of excess oxygen. The original assignment of the multiple pre-edge peaks in the O K-edge spectra originating from the different binding energies of O 1s levels of unequivalent oxygen sites is based on the single-crystal study of Nücker et al., but powder samples have since then been successfully characterized as well. Also for the Bi$_2$Sr$_2$(Y$_{1-x}$Ca$_x$)Cu$_2$O$_{8+z}$-Bi or Bi-2212 phase, it was recently demonstrated that the intensity of the pre-edge peak around 528 eV in the O K-edge XANES spectrum corresponds to the concentration of holes created in the CuO$_2$ plane with increasing Ca-substitution level. From the crystal- and redox-chemical points of view, (Pb$_{2/3}$Cu$_{1/3}$)$_3$A$_2$(R,Ca)Cu$_2$O$_{8+z}$ [(Pb$_{2/3}$Cu$_{1/3}$)$_3$-3212] (Refs. 12, 13) is one of the most interesting superconductive copper-oxide phases. The structure of the (Pb$_{2/3}$Cu$_{1/3}$)-3212 phase with a layer sequence, AO-CuO$_2$-(R,Ca)-CuO$_2$-AO-PbO-CuO$_2$-PbO, differs from that of Cu-1212 with respect to the number of charge-reservoir layers $m$. That is, in (Pb$_{2/3}$Cu$_{1/3}$)-3212 the single nonstoichiometric CuO$_2$ layer, which is the only charge-reservoir constituent in Cu-1212, is sandwiched by
two oxygen-stoichiometric PbO planes. Synthesis in an atmosphere of a low-oxygen partial pressure results in an oxygen-deficient phase with \(z<0.1\), but like Cu-1212, the (Pb\(_{2/3}\)Cu\(_{1/3}\))-3212 lattice easily accommodates oxygen atoms around the charge-reservoir Cu atom when annealed in an \(O_2\)-rich atmosphere. Oxygen loading up to \(z\approx 1.8\) is possible without destroying the structure, though no intermediate oxygen configurations between the lowest and the highest values exist. In (Pb\(_{2/3}\)Cu\(_{1/3}\))-3212, the holes that are created in the charge-reservoir block upon the entering of excess oxygen atoms in the structure, are not transferred into the CuO\(_2\)-(R,Ca)-CuO\(_2\) block but are believed to be trapped on Pb and Cu in the PbO-CuO-PbO charge reservoir. In other words, oxygen loading seems to increase the oxidation states of the charge-reservoir cations only, from +I to +II for Cu and from +II to +IV for Pb, as suggested by the results of both BVS calculations and wet-chemical analyses. This conclusion manifests itself by the fact that the charge-reservoir Cu atom remains at the monovalent state throughout the Ca-substitution range studied (\(0<x<0.5\)).

In the present paper, the continuous generation of holes into the CuO\(_2\) plane with an increasing Ca-substitution level in the oxygen-deficient (Pb\(_{2/3}\)Cu\(_{1/3}\))-3212 phase does not superconduct. Also with the oxygen-deficient configuration at \(z=0\), (Pb\(_{2/3}\)Cu\(_{1/3}\))-3212 is an antiferromagnetic semiconductor. If the \(Q\)-metal layer between the two CuO\(_2\) planes in the CuO\(_2\)-Q-CuO\(_2\) block is composed of rare-earth elements only. Only when substituting part of the trivalent R ions by divalent Ca, superconductivity arises.

In the present paper, the continuous generation of holes into the CuO\(_2\) plane with an increasing Ca-substitution level in the oxygen-deficient (Pb\(_{2/3}\)Cu\(_{1/3}\))\(_3\)Sr\(_2\)(Y\(_{1-x}\)Ca\(_x\))Cu\(_4\)O\(_{8+z}\) phase has been followed for the first time directly by means of \(O\)-edge and Cu \(L_{2,3}\)-edge XANES measurements. From the Cu \(L_{2,3}\)-edge spectra, it could furthermore be confirmed that the charge-reservoir Cu atom remains at the monovalent state throughout the Ca-substitution range studied (\(0<x<0.5\)).

II. EXPERIMENT

Six powder samples of the (Pb\(_{2/3}\)Cu\(_{1/3}\))\(_3\)Sr\(_2\)(Y\(_{1-x}\)Ca\(_x\))Cu\(_4\)O\(_{8+z}\) phase with \(x\) ranging from 0 to 0.5 were synthesized by solid-state reaction from stoichiometric mixtures of high-purity PbO, SrCO\(_3\), CaCO\(_3\), Y\(_2\)O\(_3\), and CuO powders. The powder mixtures were first calcined in air at 800 °C for 30 h and then sintered in argon at 860 °C for 20 h. The crystallinity and phase purity of the samples were checked by x-ray diffraction measurements (XRD: Philips PW 1830; CuK\(_\alpha\) radiation). The unit-cell parameters were refined from the XRD data in the \(Cnmm\) space group using a Rietveld refinement program FULLPROF. The low level of excess oxygen in the synthesized samples was confirmed by Cu(I)/(II) coulometric titrations. The samples were characterized for superconductivity properties by a superconducting quantum interference device (SQUID) magnetometer (Quantum Design MPMS-5S). The “effective” \(T^\text{c,}^{(2)}\) values were estimated from the \(\chi\)-versus-\(T\) curves, measured in a field-cooling mode under a magnetic field of 10 Oe from room temperature down to 5 K, by extrapolating the diamagnetic portion of the curves to the \(\chi=0\) level. Note that the \(T^\text{c,}^{(2)}\) value is always somewhat lower than the onset temperature of the Meissner signal, \(T^\text{c,}^{(2)}\), i.e., the temperature that is most typically referred to as \(T^\text{c}\).

The x-ray absorption experiments were carried out at the Synchrotron Radiation Research Center (Hsinchu, Taiwan) on the 6-m high-energy spherical grating monochromator beamline. All the measurements were made at room temperature using an ultrahigh vacuum chamber (10\(^{-9}\) torr) in order to avoid surface contamination. Furthermore, to minimize the surface contribution, the spectra were recorded by a bulk-sensitive x-ray fluorescence mode with a probing depth of 2000–5000 Å. For the measurement, the sample was finely crushed into powder form and homogeneously spread onto a conducting carbon-based tape. The \(O\)-edge and Cu \(L_{2,3}\)-edge x-ray fluorescence-yield spectra were recorded from the samples using a microchannel plate (MCP) detector system consisting of a dual set of MCP’s with an electrically isolated grid mounted in front of them. The grid was set to a voltage of 100 V, the front of the MCP’s to −2000 V and the rear to −200 V. The grid bias ensured that positive ions did not enter the detector, while the MCP bias ensured that no electrons were detected. The detector was located parallel to the sample surface at a distance of ~2 cm. Photons were incident at an angle of 45° with respect to the sample normal. The incident photon flux \(I_0\) was monitored simultaneously by a Ni mesh located at the exit slit of the monochromator. All the absorption measurements were normalized to \(I_0\). The photon energies were calibrated with an accuracy of 0.1 eV using the \(O\)-edge absorption peak at 530.1 eV and the Cu \(L_3\) white line at 931.2 eV of CuO reference. The monochromator resolution was set to ~0.22 and ~0.45 eV at the O 1s and Cu 2p absorption edges, respectively.

III. RESULTS AND DISCUSSION

The synthesized (Pb\(_{2/3}\)Cu\(_{1/3}\))\(_3\)Sr\(_2\)(Y\(_{1-x}\)Ca\(_x\))Cu\(_4\)O\(_{8+z}\) samples were found to be of the pure (Pb\(_{2/3}\)Cu\(_{1/3}\))-3212 phase within the detection limit of XRD throughout the Ca-substitution range applied, i.e., up to \(x=0.5\). According to the preliminary experiments, the first diffraction peaks that could not be indexed for the (Pb\(_{2/3}\)Cu\(_{1/3}\))-3212 phase appeared at \(x\approx 0.6\). Coulometric titrations confirmed that the samples were fully oxygen depleted: within the error limits of the analysis, the amount of excess oxygen \(z\) could be considered to be zero for each sample studied. No trend of decreasing oxygen content with increasing the Ca-substitution level was observed. This is in contrast to, e.g., fully oxygenated Cu(Ba,Sr)\(_2\)(R\(_1-x\)Ca\(_x\))Cu\(_2\)O\(_{6+z}\) and Bi\(_2\)Sr\(_2\)(Y\(_{1-x}\)Ca\(_x\))Cu\(_4\)O\(_{8+\delta}\) systems in which the maximum oxygen content decreases with \(x\).

The obtained samples possessed an orthorhombic structure within the whole substitution range studied. With an increasing amount of Ca(II) entering the Y(III) site, the lattice parameters \(a\) and \(b\) were found to decrease, while the \(c\) parameter increased (Table I). The expansion of the lattice along the \(c\) axis as \(x\) increases is related to the fact that the Ca\(^{2+}\) ion is larger than the Y\(^{3+}\) ion. On the other hand, the concomitant contraction along the \(a\) and \(b\) axes may be attributed to an increase in the oxidation state of the CuO\(_2\) plane. As \(x\) increased in the
Table I. The value of $T_c(x)$, the lattice parameters, $a$, $b$, and $c$, and the fitted peak areas of the O K-edge peak at $\sim 528.3$ eV ($I_{528}$) and the Cu L$_3$-edge peaks at $\sim 933.5$ eV ($I_{933}$) [Cu(II)] and $\sim 934.5$ eV ($I_{934}$) [Cu(I)] for the (Pb$_{2/3}$Cu$_{1/3}$)$_2$Sr$_2$(Y$_{1-x}$Ca$_x$)$_2$Cu$_2$O$_{8+y}$ system. Note that the slightly different shape of the x=0.4 spectrum is due to some small impurity from the conducting tape used as a sample holder. These impurity peaks centered at around 535 eV and 539 eV were subtracted from the spectrum before the fitting.

The Cu L$_{3/2}$-edge spectra in the energy range of 920–960 eV are shown in Fig. 3(a). The spectra were analyzed by fitting the peaks with Gaussian functions, as demonstrated with increasing Ca content is observed, suggesting that the Fermi level shifts to the lower energies with an increasing of the CuO$_2$-plane hole concentration. The shift is not, however, as clear as that observed for, e.g., the Bi$_2$Sr$_2$(Y$_{1-x}$Ca$_x$)$_2$Cu$_2$O$_{8+y}$ system with increasing Ca-substitution level. Around $x \approx 0.2$, the $I_{528}$-versus-$x$ relation shown in Fig. 2(a) exhibits a narrow plateau that might be due to some inhomogeneity in the distribution of Ca at the Y site. Interestingly, this is quite parallel to the trend that applies to the dependence, $T_c(x)$-versus-$x$ given in Fig. 2(b). Consequently, the $T_c(x)$-versus-$I_{528}$ relation is rather presented with the bell-shaped line, shown in Fig. 2(c), as typically assumed for the $T_c(x)$-versus-“CuO$_2$-plane hole concentration” relation of high-$T_c$ superconductors.
for the spectra of the \(x = 0\) and 0.5 samples in Fig. 3(b). The results are given in Table I. Two narrow peaks centered at \(-932.0\) and \(-952.0\) eV dominate the spectra of all the six samples. These peaks are due to formally divalent copper states, i.e., transitions from the Cu \((2p_{3/2,1/2})^3d^9\) ground states into the Cu \((2p_{3/2,1/2})^3d^{10}\) excited states, where \((2p_{3/2,1/2})\) denotes a \(2p_{3/2}\) or \(2p_{1/2}\) hole. With an increasing degree of Ca substitution, a feature due to the formally trivalent copper in the CuO\(_2\) plane appears on the high-energy side of the 932.0 eV peak. This high-energy shoulder at \(-933\) eV, reported for the first time for the CuBa\(_2\)YCu\(_2\)O\(_{6+z}\) phase as a consequence of oxygen doping,\(^{27}\) has been interpreted as transitions from the Cu \((2p_{3/2})^3d^9L\) ground states into the Cu \((2p_{3/2})^3d^{10}L\) excited states, where \(L\) denotes a ligand hole in the O 2p orbital. With an increasing Ca-substitution level, the 932.0 eV peak becomes increasingly asymmetric, indicating that the amount of formally trivalent copper continuously increases (Table I). However, as compared to the fully-oxygenated CuBa\(_2\)YCu\(_2\)O\(_{6+z}\) phase, the shoulder is less prominent even in the spectrum of the
most heavily substituted sample ($x = 0.5$). This is due to the fact that in (Pb$_{2/3}$Cu$_{1/3}$)$_2$Sr$_2$(Y$_{1-x}$Ca$_x$)Cu$_2$O$_{8+z}$ with $z = 0$, only the CuO$_2$-plane copper is in an oxidation state higher than +II, while in CuBa$_2$YCuO$_{6+z}$ with $z \approx 1$, not only the CuO$_2$ plane but also the CuO$_2$ chain contains formally trivalent copper atoms.

In the Cu $L_{23}$-edge spectra, an additional peak around 934.5 eV, characteristically observed in monovalent copper compounds, is seen for all the samples studied. This peak arises from the Cu 3$d_{x^2-y^2}$O 2$p_z$ hybrids between the charge-reservoir copper atom and the PbO-layer oxygen atom. The intensity of the 934.5 eV peak remains essentially unchanged upon increasing the Ca-substitution level (Table I), revealing that the holes generated through the Ca(II)-for-Y(III) substitution are not transferred to the charge-reservoir copper atom, but remain solely in the CuO$_2$ plane.

The present XANES results clearly established that in Ca-substituted oxygen-depleted (Pb$_{2/3}$Cu$_{1/3}$)$_2$-3212, copper atoms with oxidation states below and above $+II$ coexist in the same structure: the CuO$_2$-plane Cu is in the mixed $+II$/$+III$ state while the charge-reservoir Cu possesses a twofold linear coordination to the nearest PbO-layer oxygen atoms and is monovalent (cf. charge-reservoir Cu in CuBa$_2$CuO$_4$). This conclusion is consistent with charge-balance considerations and the results of BVS calculations and chemical analyses. Note that, the Pb atom with five nearest-neighbor oxygen atoms is believed to be divalent. That the CuO$_2$ plane can keep the holes created through Ca substitution violates against the redox-potential scheme: based on the redox potentials of the Pb(II)/(IV), Cu(I)/(II) and Cu(II)/(III) couples, Pb(II) and Cu(I) should be oxidized more easily than Cu(II). In a solid matrix, however, the redox-potential scheme applies only when the number of nearest-neighbor counter ions allows the predicted changes in the oxidation state. The fact that in the oxygen-depleted (Pb$_{2/3}$Cu$_{1/3}$)$_2$-3212 phase, the coordination numbers of the charge-reservoir Cu and Pb atoms are low, i.e., 2 and 5, respectively, is thus crucially important in terms of facilitating the hole doping of the CuO$_2$ plane. At the twofold/fivefold coordination Cu/Pb cannot be oxidized beyond the oxidation state $+I$/$+II$. On the other hand, the incorporation of oxygen in the Ca-substituted (Pb$_{2/3}$Cu$_{1/3}$)$_2$-3212 phase would kill the superconductivity by increasing the coordination numbers of the charge-reservoir Cu and Pb atoms and thereby enabling the CuO$_2$-plane holes to move to the PbO-CuO$_2$-PbO charge-reservoir block.

Finally, it is interesting to compare the effectiveness of Ca substitution in oxygen-depleted (Pb$_{2/3}$Cu$_{1/3}$)$_2$-3212 in terms of increasing the CuO$_2$-plane hole concentration and thereby the value of $T_c$ to data previously obtained for other $M$-$m$-$2(n-1)n$ phases with a two-CuO$_2$-plane structure, i.e., $n = 2$. In Fig. 4, the value of $T_c$ is plotted against the Ca-substitution level $x$ for the present (Pb$_{2/3}$Cu$_{1/3}$)$_2$Sr$_2$(Y$_{1-x}$Ca$_x$)Cu$_2$O$_{8+z}$ ($z = 0$) system together with the systems, Cu$_2$(Ba$_{0.8}$Sr$_{0.2}$)$_2$(Yb$_{1-x}$Ca$_x$)Cu$_2$O$_{8+z}$ (Cu$_{1212}$; $z = 0$), and Bi$_2$Sr$_2$(Y$_{1-x}$Ca$_x$)Cu$_2$O$_{8+z}$ (Bi$_{2212}$; $\delta$ decreases from 0.52 to 0.26 with an increase of $x$ from 0 to 1). In the case of the Bi$_{2212}$ system with a strongly oxygenated BiO$_{1+\delta}$-BiO$_{1+\delta}$ charge reservoir, quite a high Ca substitution level is required for the appearance of superconductivity, i.e., $x \approx 0.5$ (Fig. 4). This is due to two different factors: by means of redox-chemical analyses it has been shown that with increasing $x$ (i) the oxygen content decreases, and (ii) the valence of Bi increases. In other words, each Ca atom entering the structure produces on average less than one electron hole since the concomitant decrease in the oxygen content partially counteracts the effects of the divalent-for-trivalent substitution. Furthermore, the produced holes are not quantitatively directed into the CuO$_2$ plane but are partly accommodated in the BiO$_{1+\delta}$-BiO$_{1+\delta}$ charge reservoir. On the other hand, in the (Pb$_{2/3}$Cu$_{1/3}$)$_2$-3212 and Cu$_{1212}$ systems with the oxygen-depleted charge reservoirs, PbO-Cu-Pb and Cu, respectively, the holes produced by means of Ca substitution are directed efficiently into the CuO$_2$ plane. Consequently, superconductivity appears, as seen in Fig. 4, at a much lower Ca content of $x \approx 0.2$ than in the case of the Bi$_{2212}$ phase.

IV. CONCLUSION

By means of O $K$-edge and Cu $L_{23}$-edge XANES measurements it has been directly established that the holes generated through the Ca(II)-for-Y(III) substitution in the oxygen-depleted (Pb$_{2/3}$Cu$_{1/3}$)$_2$Sr$_2$(Y$_{1-x}$Ca$_x$)Cu$_2$O$_{8+z}$ phase are solely transferred into the CuO$_2$ plane. As a manifestation for the increase in the CuO$_2$-plane hole concentration, two indicative features appeared in the measured O $K$-edge and Cu $L_{23}$-edge absorption spectra, i.e., the pre-edge peak at $\approx 528.3$ eV in the former and the high-energy shoulder of the 932.0 eV main peak in the latter spectra. On the other hand, the fact that the intensity of the 934.5 eV peak in the Cu $L_{23}$-edge spectra remained unchanged confirmed that the charge-reservoir Cu atom is not oxidized upon the Ca substitution. The present XANES results are in good agreement with the charge-distribution scheme proposed for the (Pb$_{2/3}$Cu$_{1/3}$)$_2$Sr$_2$(Y$_{1-x}$Ca$_x$)Cu$_2$O$_{8+z}$ system in previous...
works based on structural considerations and wet-chemical analysis.
