**Abstract-** In this paper, we present an effective emitter passivation scheme using SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub>/SiN<sub>x</sub> stacks. Our study shows that SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub>/SiN<sub>x</sub> stacks can well passivate both p<sup>+</sup> and n<sup>+</sup> emitters due to an excellent chemical passivation combined with a weak field-effect passivation. Good quality boron and phosphorus emitters were achieved over a broad emitter-doping range, as demonstrated by post-fired emitter saturation current of 20 and 30 fA·cm<sup>-2</sup>, respectively. Based on the results obtained with SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub>/SiN<sub>x</sub> emitter passivation, we present an industrial roadmap for a p-PERT bifacial cell structure. Using this roadmap, we demonstrate industrial p-PERT bifacial cells with front side efficiency of 20.5%, rear side efficiency of 19.8% (bifaciality factor  $BF=0.98$ ) for rear textured cells and 17.5% ( $BF=0.85$ ) for rear planar cells. In particular, the cells with bifacial SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub>/SiN<sub>x</sub> passivation on both p<sup>+</sup> and n<sup>+</sup> emitters also demonstrate promising performance and a simplified cell process. The results show that SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub>/SiN<sub>x</sub> emitter passivation scheme is a promising candidate for photovoltaic industry.

## 1. Introduction

As photovoltaic (PV) energy is to become one of the main renewable energy sources in the next decades, the industry needs to pay attention to mass production of cost-efficient solar cells. Emitter (n<sup>+</sup> and p<sup>+</sup>) passivation is an important step towards this goal. Dielectric films, e.g. SiN<sub>x</sub> [1–3], Al<sub>2</sub>O<sub>3</sub> [4–8] and SiO<sub>2</sub> [1,9–15], can well combine both field-effect and chemical passivation, and as a result they have been successfully applied into surface passivation of crystalline Si (c-Si) solar cells in the lab and industry. For surface passivation from the solar cell operation point of view, the most important benchmark is to achieve a good "final" passivation, i.e. after co-firing for screen-printed Si solar cells, rather than a good initial or intermediate passivation. It is well known that single layer dielectric passivation such as Al<sub>2</sub>O<sub>3</sub> or SiO<sub>2</sub> tends to suffer from firing stability issues [7,16–20]. This means that a high intermediate passivation level during cell processes can be obtained, but it cannot be maintained when cell fabrication is completed. Previous studies indicate that the poor firing stability of thin Al<sub>2</sub>O<sub>3</sub> (< 20 nm) is attributed mainly to an increase in interface defect density ( $D_{it}$ ) while fixed charge density ( $Q_f$ ) of Al<sub>2</sub>O<sub>3</sub> is found to be less affected [7,16]. Further, the increased  $D_{it}$  is due to dissociation of interfacial Si–hydrogen bonds at elevated temperatures [21]. A thicker Al<sub>2</sub>O<sub>3</sub> (e.g. >30 nm) can improve firing stability to some extent, however such thick films suffer from blistering [22,23] and are not cost-efficient. Dielectric stacks, e.g. SiO<sub>2</sub>/SiN<sub>x</sub>, Al<sub>2</sub>O<sub>3</sub>/SiN<sub>x</sub>, can improve the final passivation, which has been attributed mainly to hydrogen (H) passivation provided by the stacks [7,17,21,24–26].

Another surface passivation candidate with a good firing stability are SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub> stacks, which have been recently studied by some groups. According to Ref.s [27–31], the space-charge field can be regulated via tuning the effective charge density ( $Q_{eff}$ ) of the whole stacks by changing the SiO<sub>2</sub> interlayer thickness ( $d_{SiO_2}$ ). Furthermore, SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub> stacks can provide H passivation and thus a good chemical passivation of the Si interface [32–35]. The interfacial SiO<sub>2</sub> is crucial for the excellent chemical

passivation [4,7,36,37] and it can be either grown in-situ during atomic layer deposition (ALD) and post-anneal or grown ex-situ using a separate thermal oxidation, ALD, plasma enhanced chemical vapor deposition (PECVD) and chemical oxidation processes [4,7,28,30,36,38]. Thus, due to an excellent chemical passivation combined with a weak field-effect passivation, SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub> can well passivate both n-Si [29,32,39–41] and p-Si [29,30,42]. Despite the extensive material-level studies on SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub> stacks, their application in screen-printed industrial Si solar cells is limited. This requires systematic studies on changes in passivation mechanisms during cell fabrication processes and their impact on cell performance. Moreover, since SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub> can well passivate both n<sup>+</sup>-Si and p<sup>+</sup>-Si, it should bring a clear cost benefit in various cell structures such as IBC (Interdigitated Back Contact) [14], PERT (Passivated Emitter and Rear Totally-diffused) [11,12] and bifacial cells.

In this paper, we study the applicability of SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub>/SiN<sub>x</sub> stacks to screen-printed industrial Si solar cells. We start by studying the emitter passivation mechanisms of different stacks, namely Al<sub>2</sub>O<sub>3</sub>, Al<sub>2</sub>O<sub>3</sub>/SiN<sub>x</sub>, SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub>, SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub>/SiN<sub>x</sub> and SiO<sub>2</sub>/SiN<sub>x</sub>, with special focus on the changes caused by the thermal treatments typically present in industrial solar cell fabrication, as well as in pursuit of the best final (after firing) emitter passivation quality. Then we apply the optimized SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub>/SiN<sub>x</sub> stacks to p-PERT bifacial cells. While p-PERT bifacial cells may seem somewhat expensive cell architecture due to relatively immature boron doping technology, especially when compared to bifacial PERC<sup>+</sup> cells [43] that are based on more mature industrial PERC (Passivated Emitter and Rear Cell [13]) concept, p-PERT bifacial structure has the following benefits: 1) under this premise of the same front-side cell efficiency, boron-doped back-surface field (BSF) provides higher rear-side cell efficiency (thus higher bifaciality factor [44]) than Al doping; 2) the compatibility of structure and process with n-PERT and 3) the studied SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub>/SiN<sub>x</sub> stacks can passivate both boron (B) and phosphorous (P) emitters present in the structure.

## 2. Experimental

In this study, both minority carrier lifetime (hereinafter shortened as lifetime) and solar cell experiments were carried out. For the B-emitter lifetime experiments, we used pseudo-square 6-inch Czochralski (Cz) n-Si wafers from the same ingot, with bulk resistivity  $\rho_{\text{bulk}} \approx 2 \Omega \cdot \text{cm}$  and a starting thickness of 190  $\mu\text{m}$ . For the P-emitter lifetime experiments and cell experiments, we used standard pseudo-square 6-inch Cz p-Si wafers with  $\rho_{\text{bulk}} = 2\text{-}3 \Omega \cdot \text{cm}$  and a starting thickness of 190  $\mu\text{m}$ , taken from the same ingot. The lifetime and cell samples are 5 and  $\sim 50$  for each group, respectively.

The sequence of the lifetime experiments is shown in Fig. 1. Symmetrical p<sup>+</sup>np<sup>+</sup> (n<sup>+</sup>pn<sup>+</sup>) samples were prepared to investigate the passivation quality of p<sup>+</sup> (n<sup>+</sup>) emitters. After saw damage removal (SDR) using NaOH solution and a pre-cleaning using HCl-HF solution, B or P implantation was performed using Intevac's ENERGi industrial implanters and it was followed by an in-situ oxidation anneal in a tube furnace. The B implantation used B<sub>2</sub>H<sub>6</sub> (15% B<sub>2</sub>H<sub>6</sub> + 85% H<sub>2</sub>) as the ion source with the implant energy  $E=10 \text{ keV}$ , dose  $D=1.3\text{-}3.8 \cdot 10^{15} \text{ cm}^{-2}$  and anneal temperature  $T=1050^\circ\text{C}$ . The P implantation used PH<sub>3</sub> (100% pure) as the ion source with the  $E=7 \text{ keV}$ ,  $D=2.2\text{-}3.5 \cdot 10^{15} \text{ cm}^{-2}$  and anneal  $T=840^\circ\text{C}$ . After etching the thermally grown SiO<sub>2</sub> using dilute HF solution, sheet resistance  $R_{\square}$  of B emitter ( $R_{\square\text{B}}$ ) and P emitter ( $R_{\square\text{P}}$ ) was measured by four-point probe on n-Si and p-Si monitor wafers, respectively. Junction profiles and parameters (surface doping concentration  $N_{\text{surf}}$ , junction depth  $X_j$ ) were measured using secondary ion mass spectroscopy. The  $N_{\text{surf}}$  are electrically activated by confirming with Ssuprem3.1 simulations via comparing the total and active dopants profiles. Al<sub>2</sub>O<sub>3</sub> or Al<sub>2</sub>O<sub>3</sub>/SiN<sub>x</sub> stacks were then deposited on the wafers for further passivation. A dilute HCl-HF pre-Al<sub>2</sub>O<sub>3</sub> clean was performed for the Al<sub>2</sub>O<sub>3</sub>/(SiN<sub>x</sub>) stacks, while no pre-clean was performed for the SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub>/(SiN<sub>x</sub>) stacks. Al<sub>2</sub>O<sub>3</sub> was

deposited using Beneq's P800 industrial batch thermal ALD with  $\text{Al}(\text{CH}_3)_3$  trimethylaluminium (TMA) and ozone ( $\text{O}_3$ ) precursors,  $T=200^\circ\text{C}$  and 10 nm (90 cycles) film thickness. Post- $\text{Al}_2\text{O}_3$  anneal was performed in a tube furnace in  $\text{N}_2$  atmosphere at  $425^\circ\text{C}$  for 25 min.  $\text{SiN}_x$  was deposited using Roth-Rau's parallel-plate type PECVD (SINA<sup>L</sup>) at  $400^\circ\text{C}$ . Rapid thermal process (RTP) firing was performed using Despatch's (Ultraflex) firing furnace, with the real peak  $T\approx 750^\circ\text{C}$ , belt speed  $\approx 6250$  cm/min and in compressed air.

Fig. 1. The sequence of the lifetime experiments in this study.

Effective lifetime and emitter saturation current ( $J_{0e}$ ) were determined by photo conductance decay using a Sinton WCT120 tester [45]. The basic settings are: 1) generalized mode; 2)  $5 \cdot 10^{15} \text{ cm}^{-3}$  specified minority carrier density (MCD) for effective lifetime measurement; 3)  $J_{0e}$  extracted using Kane and Swanson's method [46] by selecting a suitable MCD within the emitter recombination-dominant region (typical range of  $\pm 30\%$  around  $10\times$  the base doping concentration) to well match the fitted  $J_{0e}$  curves; 4) optical constant selected depending on reflectance and transmittance of Si surface and dielectrics (0.7 for (100)-oriented Si surface, 0.7-0.95 for  $(\text{SiO}_2)/\text{Al}_2\text{O}_3/(\text{SiN}_x)$ ) [45]. By combining the Sinton tester with iodine passivation [47], the measured bulk lifetime of the used Cz n-Si and p-Si is  $\sim 750$  and  $\sim 250$   $\mu\text{s}$ , respectively. Film thickness ( $d_{\text{film}}$ ) and refractive index were measured with a Suntech ellipsometer at a wavelength of 633 nm.  $Q_{\text{eff}}$  of dielectrics was measured by Semilab SDI PV2000 using the contactless COCOS (corona oxide characterization of semiconductors) method [48]. In this study,  $Q_{\text{eff}}$  is defined as the sum of the total negative and positive charge density in the dielectrics that causes the space-charge field in the Si. Because  $Q_{\text{eff}}$  cannot be directly measured on the emitter surface using the COCOS method, we instead measured  $Q_{\text{eff}}$  on p-Si and n-Si wafer substrates to evaluate  $p^+$  and  $n^+$  emitter, respectively.

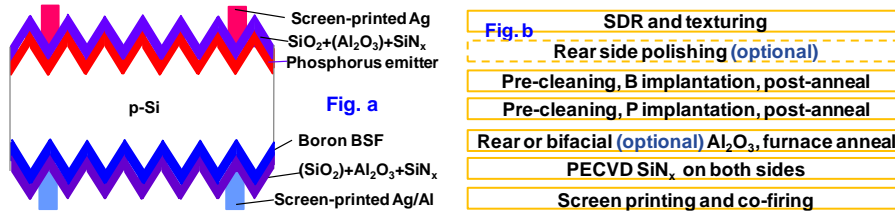

Fig. 2. The p-PERT bifacial cell structure (rear textured surface sketched) and process.

The p-PERT bifacial cell structure and process are shown in Fig. 2. The cell rear surface was designed as textured or planar based on different application requirements. After SDR and random-pyramids texturing, the cell rear was optionally (i.e. for some groups of the wafers) single side polished using  $\text{HNO}_3\text{-HF-H}_2\text{SO}_4$  solution in a RENA's (RENA InOxSide HT) wet bench. Front  $n^+$  emitter ( $R_{\square P}=88 \Omega/\square$ ) and rear  $p^+$  BSF ( $R_{\square B}=69 \Omega/\square$ ) were formed via P and B implantation and post implantation anneal. During the post P implantation anneal, a thin  $\text{SiO}_2$  was grown in-situ to passivate the implanted junctions on both sides. PECVD  $\text{SiN}_x$  or ALD  $\text{Al}_2\text{O}_3$ /PECVD  $\text{SiN}_x$  were deposited on both sides of the cells for antireflection (ARC) and surface passivation.  $\text{Al}_2\text{O}_3$  process was followed by a furnace anneal in  $\text{N}_2$  atmosphere at  $425^\circ\text{C}$  for 25 min. Screen printing and co-firing were used for metallization (5 busbars each side). In addition, the pre- $\text{Al}_2\text{O}_3$  treatments were: 1) the thin  $\text{SiO}_2$  in the  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  stacks was

grown in-situ during the post P implantation anneal and no pre-cleaning was performed on cells with SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub>/SiN<sub>x</sub>; 2) for cells with p<sup>+</sup> emitter/Al<sub>2</sub>O<sub>3</sub>/SiN<sub>x</sub>, a ~68 nm SiN<sub>x</sub> was deposited on the cell front after the post P implantation anneal, to protect the front SiO<sub>2</sub> in the subsequent pre-Al<sub>2</sub>O<sub>3</sub>-cleaning. Before Al<sub>2</sub>O<sub>3</sub> process, the rear thin SiO<sub>2</sub> was removed by a dip in 0.5% HF+HCl solution for ~15-30 s, during which the front 68 nm SiN<sub>x</sub> was etched <1 nm. The as-fabricated cell performance of front side (under front illumination only) and rear side (under rear illumination only) were independently measured with a Berger I-V tester under standard global AM1.5 spectrum, 1000 W·m<sup>-2</sup>, at 25 °C.

### 3. Result and Discussion

#### 3.1 Lifetime results: effective SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub>/SiN<sub>x</sub> passivation on B and P emitter

In order to implement the lifetime results to the solar cells, the d<sub>film</sub> of each layer of the stacks and thermal treatments were designed considering the practical limitations related to cell structure and process. Hence, the lifetime results can reflect to some extent the cell performance.

First, we study the passivation of B emitter. The  $J_{0e}$  of B emitter (hereinafter denoted as  $J_{0,p+}$ ) with different stacks as a function of the undergone thermal processes, is shown in Fig. 3. Right after the Al<sub>2</sub>O<sub>3</sub> process, there is scarcely any passivation effect on the B emitter without SiO<sub>2</sub>, while there is weak passivation provided by the 7 nm SiO<sub>2</sub>. Only considering the  $J_{0,p+}$  after the post-Al<sub>2</sub>O<sub>3</sub> furnace anneal (hereinafter denoted as PAFA), Al<sub>2</sub>O<sub>3</sub>/(SiN<sub>x</sub>) is significantly better than SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub>/(SiN<sub>x</sub>). The increased  $J_{0,p+}$  of each group after PECVD SiN<sub>x</sub> is due to the plasma bombardment induced damage on Al<sub>2</sub>O<sub>3</sub>. The subsequent firing can both cure this damage and promote H passivation from the stacks, leading to a significantly recovered passivation level. The post-fired  $J_{0,p+}$  with SiO<sub>2</sub> is clearly better than without SiO<sub>2</sub>. Furthermore, a SiN<sub>x</sub> capping layer can further decrease  $J_{0,p+}$ . It was confirmed in our study [23] that, for the stacks used here, ≤10 nm ALD Al<sub>2</sub>O<sub>3</sub> (TMA and O<sub>3</sub> based) scarcely suffers from blistering after undergoing the thermal processes in the lifetime and cell experiments. Thus, the better post-fired  $J_{0,p+}$  of SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub>/(SiN<sub>x</sub>) cannot be attributed to a reduced blistering problem. Overall, the results indicate that the thin SiO<sub>2</sub> between p<sup>+</sup>-Si and Al<sub>2</sub>O<sub>3</sub> as well as the SiN<sub>x</sub> capping layer can improve the firing stability of Al<sub>2</sub>O<sub>3</sub>, thus decreasing  $J_{0,p+}$ .

The corresponding  $J_{0e}$  results on P emitter ( $J_{0,n+}$ ) are shown in Fig. 4. The  $J_{0,n+}$  after PECVD SiN<sub>x</sub> is not shown since it has a similar trend as  $J_{0,p+}$  (Fig. 3). In all cases, bare Al<sub>2</sub>O<sub>3</sub>/(SiN<sub>x</sub>) provided poor passivation, while SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub>/(SiN<sub>x</sub>) achieved good  $J_{0,n+}$ , especially after firing (even slightly better than SiO<sub>2</sub>/SiN<sub>x</sub>). Similarly to B emitters, a SiN<sub>x</sub> capping layer further decreases  $J_{0,n+}$ . Overall, the results indicate that the thin SiO<sub>2</sub> between n<sup>+</sup>-Si and Al<sub>2</sub>O<sub>3</sub> is critical to decrease  $J_{0,n+}$ , and that the SiN<sub>x</sub> capping layer can improve the firing stability of Al<sub>2</sub>O<sub>3</sub>.

Fig. 5 shows the  $J_{0,p+}$  ( $J_{0,n+}$ ) and active N<sub>surf</sub> as a function of R<sub>□</sub> and different stacks. Over a broad R<sub>□B</sub> range, the Al<sub>2</sub>O<sub>3</sub>/(SiN<sub>x</sub>) stacks could achieve a good  $J_{0,p+}$  right after PAFA, but they did not maintain it after firing, thus implying a cell performance loss. In comparison, the SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub>/SiN<sub>x</sub> stacks achieved a good final post-fired  $J_{0,p+}$  or  $J_{0,n+}$  over a broad R<sub>□</sub>-range, as demonstrated by post-fired  $J_{0,p+} = 20-50$  fA·cm<sup>-2</sup> with R<sub>□B</sub>-range of 115-60 Ω/□ and post-fired  $J_{0,n+} = 30-50$  fA·cm<sup>-2</sup> with R<sub>□P</sub>-range of 100-70 Ω/□. It is worth noting that, such results were also found in BBr<sub>3</sub>- or POCl<sub>3</sub>-diffused emitters in our unpublished study. The above results are also consistent with Ref.s of [29,30,32,39–42], which have mainly focused on the lab-scale research and are based on different research perspectives, showing effective surface passivation of p-Si and n-Si using SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub>/(SiN<sub>x</sub>) synthesized by various methods.

Fig. 3.

Fig. 4.

Fig. 3. Measured  $J_{0,p+}$  (average) with different stacks as a function of the thermal processes. B-emitter parameters:  $N_{\text{surf}} \approx 1.2 \cdot 10^{19} \text{ cm}^{-3}$ ,  $X_f \approx 2.82 \text{ } \mu\text{m}$ ,  $R_{\square} = 69 \text{ } \Omega/\square$ .

Fig. 4. Measured  $J_{0,n+}$  (average) with different stacks as a function of the thermal processes. P-emitter parameters:  $N_{\text{surf}} \approx 8.8 \cdot 10^{19} \text{ cm}^{-3}$ ,  $X_f \approx 0.30 \text{ } \mu\text{m}$ ,  $R_{\square} = 100 \text{ } \Omega/\square$ . The samples with the  $\text{SiO}_2/\text{SiN}_x$  stacks did not undergo the PAFA.

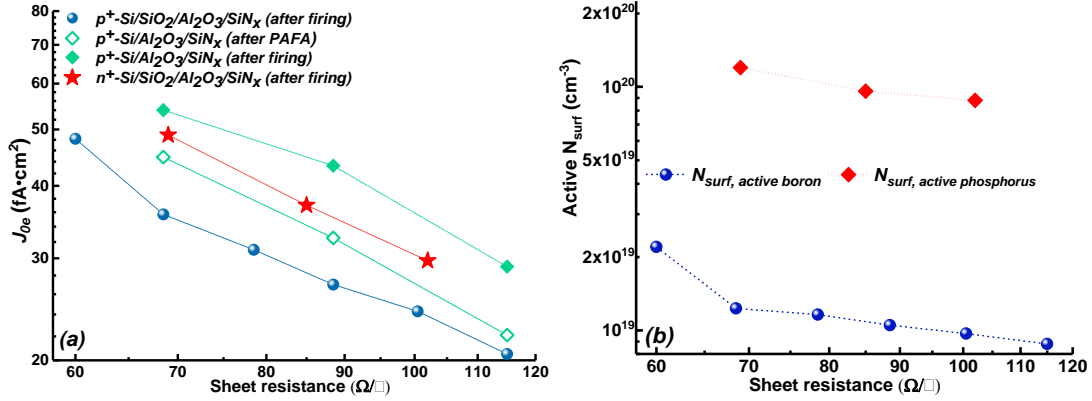

Fig. 5. Measured  $J_{0e}$  (a) and active  $N_{\text{surf}}$  (b) as a function of the  $R_{\square}$  and different stacks. The samples underwent the processes in Fig. 1.  $d_{\text{film}}$  of each layer is shown in Fig.s 3-4. The lines serve as a guide to the eye.

### 3.2 $p^+$ and $n^+$ emitter passivation mechanisms of $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$ stacks

The effective passivation of  $p^+$  and  $n^+$  emitters using  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  stacks should be linked to a good chemical passivation, a good field-effect passivation, or both. In this section, in order to further explain the lifetime results, we investigated the emitter passivation mechanisms of different dielectric stacks by combining experimental and simulation results.

#### 3.2.1 Changes in field-effect and chemical passivation during the thermal processes

First we studied the changes in field-effect passivation of each stacks during the thermal processes by measuring  $Q_{\text{eff}}$  as shown in Fig. 6. It is seen that the  $Q_{\text{eff}}$  of  $\text{Al}_2\text{O}_3/(\text{SiN}_x)$  on both  $p^+$  and  $n^+$  emitter was  $-2.5 \cdot 10^{12} \text{ cm}^{-2}$  after PAFA; while a 7 nm  $\text{SiO}_2$  interlayer decreased the negative  $Q_{\text{eff}}$  by a factor of 3.5 and 11.4 on  $p^+$  and  $n^+$  emitter, respectively. Further, after a full activation of the negative  $Q_f$  of  $\text{Al}_2\text{O}_3$  by PAFA, the subsequent PECVD  $\text{SiN}_x$  and firing hardly affected  $Q_{\text{eff}}$ . A  $\text{SiN}_x$  capping layer on top of  $\text{Al}_2\text{O}_3$  also did not affect  $Q_{\text{eff}}$ . The charge levels are similar between  $p^+$  and  $n^+$  emitters despite a slight difference. The results are consistent with Ref.s [27–31]. The tuning of  $Q_{\text{eff}}$  by the  $\text{SiO}_2$  interlayer follows a model with two regimes as a function of  $d_{\text{SiO}_2}$ , i.e. 1) dominated by the tunneling of electrons from Si through  $\text{SiO}_2$  into  $\text{Al}_2\text{O}_3$  defects states near  $\text{SiO}_2/\text{Al}_2\text{O}_3$  interface for  $d_{\text{SiO}_2} < d_0$  (where  $d_0$  is the threshold thickness

for zero- $Q_{eff}$  of the  $\text{SiO}_2/\text{Al}_2\text{O}_3/(\text{SiN}_x)$  stacks) and 2) dominated by charges intrinsic to the  $\text{SiO}_2$  film for  $d_{\text{SiO}_2} > d_0$ . Due to different positive  $Q_f$  in the  $\text{SiO}_2$ , different  $\text{SiO}_2$  synthesis methods result in different  $d_0$ . In this study, 7 nm is lower than  $d_0$  of thermally grown  $\text{SiO}_2$ , and thus the stacks show a negative  $Q_{eff}$ . The difference in  $Q_{eff}$  between p-Si and n-Si in case of  $\text{SiO}_2/\text{Al}_2\text{O}_3/(\text{SiN}_x)$  is due to the different effective tunneling barrier thickness, which is caused by the different band structure formed at the Si/ $\text{SiO}_2$  interface when band bending occurs due to the presence of built-in charges [28]. Additionally, as found in our unpublished study and consistent with Ref. [49], an excessive thermal budget could also reduce to some extent the already fully activated negative  $Q_f$  of  $\text{Al}_2\text{O}_3$ . In this study, the thermal budget of the subsequent remote PECVD  $\text{SiN}_x$  (400°C, ~10 min process time) and RTP firing is acceptable and only very slightly reduced the negative  $Q_f$  of  $\text{Al}_2\text{O}_3$  (from  $-2.5 \cdot 10^{12}$  to  $-2.4 \cdot 10^{12} \text{ cm}^{-2}$ ). Therefore, the  $Q_{eff}$  of the  $(\text{SiO}_2)/\text{Al}_2\text{O}_3/(\text{SiN}_x)$  stacks was nearly unchanged in these thermal treatments.

In summary, for all stacks, the nearly unchanged  $Q_{eff}$  after the PAFA indicated a nearly unchanged field-effect passivation in the subsequent thermal processes, for both B and P emitter. Hence, the changes in emitter passivation quality ( $J_{0e}$ ) are attributed mainly to the changes in chemical passivation. In order to gain further insights, calculations and simulations are reported in the following. Then, we discuss the parameters combining experimental results with simulations.

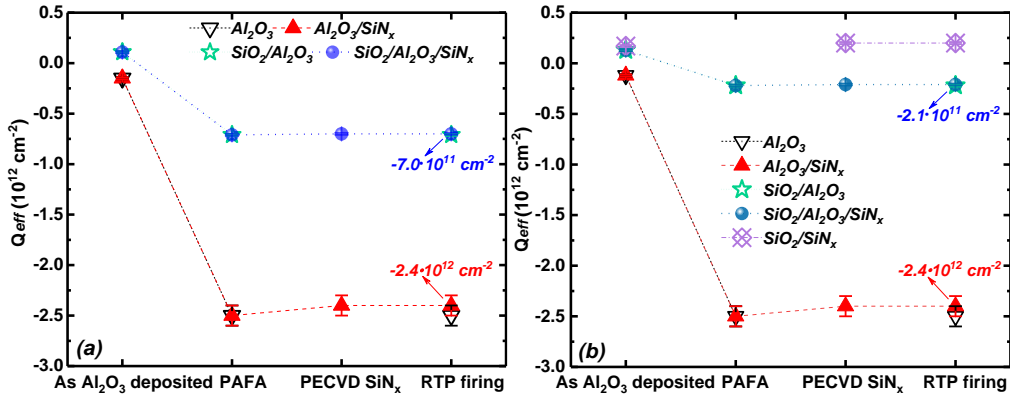

Fig. 6. The measured  $Q_{eff}$  of all stacks as a function of the thermal processes:  $Q_{eff}$  measured on (a) p-type and (b) n-type Si substrate.  $Q_{eff}$  error is  $\sim 1 \cdot 10^{10}$  ( $1 \cdot 10^{11}$ )  $\text{cm}^{-2}$  with the  $Q_{eff}$  in the order of  $10^{11}$  ( $10^{12}$ )  $\text{cm}^{-2}$ .  $d_{\text{film}}$  of each layer as in Figs 3-4.

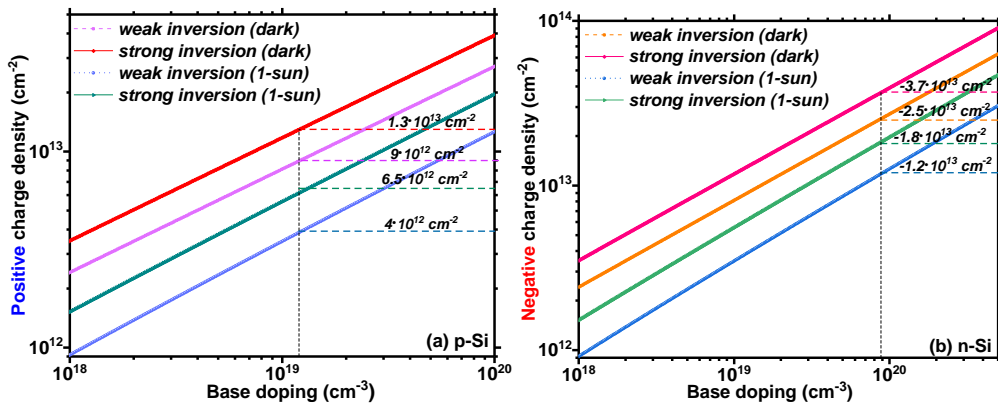

Fig. 7. Calculated threshold charge density (under dark and 1-sun illumination) for weak and strong inversion in p-Si (a) and n-Si (b) as a function of base doping density. The corresponding threshold charge density for inversion of the  $p^+$  and  $n^+$  emitter in this study (see the emitter parameters in Figs 3-4) have been marked.

Different  $Q_{eff}$  at Si/dielectrics interface can form an accumulation, depletion or inversion layer on Si surface, which induces different mechanisms of field-effect passivation [20]. An inversion induced field-effect passivation is undesirable in solar cells due to association with a lifetime reduction at low injection levels ( $<10^{15} \text{ cm}^{-3}$ , within the operating regime of solar cells) as well as potential parasitic shunting [1,29,50]. Thus, we do not discuss this case here. In order to provide a necessary support for this study, a threshold charge density for weak and strong inversion in p- and n-Si as a function of base doping density was calculated (Fig. 7) by solving Poisson's equation in one dimension [20,51]. Considering the importance of both dark characteristics and practical operating conditions of solar cells, the calculation was performed at two typical conditions, i.e. under dark and under 1-sun illumination. According to Figs. 6-7, the  $Q_{eff}$  in any of the stacks is not enough to invert the emitters in this study.

PC1D simulations were performed to investigate the changes in chemical passivation of each stack in the thermal processes. The updated PC1Dmod V6.2 software developed by Haug *et al.* [52] was used, which implements the most recent models mentioned in Ref.s [52–55]. After inputting substrate and emitter parameters, one of the following three parameters,  $S_n$  (or  $S_p$ ),  $Q_{eff}$  and  $J_{0e}$ , was extracted by fixing the other two. The input  $Q_{eff}$  and  $J_{0e}$  were the measured results when they were used to extract the others. The surface recombination velocity for electrons (holes),  $S_n$  ( $S_p$ ) is proportional to surface state density [1], and thus is determined by both  $N_{surf}$  and chemical passivation. Field-effect passivation is controlled by  $Q_{eff}$ . Using the above method, the  $S_n$  ( $S_p$ ) as a function of the thermal processes and different stacks are shown in Figs. 8-a and 9-a (corresponding to Figs. 3 and 4, respectively). Here, the PC1D simulation error of  $S_n$  and  $S_p$  resulting from the error of the input  $Q_{eff}$  measured by COCOS is within 0.7% (4.8%) with  $Q_{eff}$  in the order of  $10^{11}$  ( $10^{12}$ )  $\text{cm}^{-2}$ . The simulation error is small and thus not shown in the figures. To further understand the passivation mechanisms of different stacks, the simulated  $J_{0p+}$  ( $J_{0n+}$ ) contour plot as a function of  $Q_{eff}$  and  $S_n$  ( $S_p$ ) is shown in Fig. 8-b (9-b), which reveals the basic rules of the comprehensive effect of field-effect and chemical passivation on the overall emitter passivation ( $J_{0e}$ ). In Fig. 8-b, typical combinations (a, b, c, d, e) of parameters of field-effect and chemical passivation to reach a  $J_{0p+} = 36 \text{ fA}\cdot\text{cm}^{-2}$  (the best  $J_{0p+}$  in Fig. 3) are marked, which will be discussed in Sec. 3.2.2.

Firstly, a further explanation on Fig. 3 (B emitter) is presented by combining with the analysis of Fig. 8. As discussed above, the changes in  $J_{0p+}$  with thermal processes are attributed mainly to the changes in chemical passivation ( $S_n$ ). For the  $\text{Al}_2\text{O}_3/\text{SiN}_x$  stacks, the increased  $J_{0p+}$  from PAFA to post-firing is due to a decreased chemical passivation level with  $S_n$  increasing by a factor of 1.2. For the  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  stacks, the decreased  $J_{0p+}$  from PAFA to post-firing is due to an improved chemical passivation with  $S_n$  decreasing by a factor of 3.75. Further, for the  $\text{Al}_2\text{O}_3/\text{SiN}_x$  stacks, the strong negative-charge field-effect passivation ( $Q_{eff} \approx -2.4 \cdot 10^{12} \text{ cm}^{-2}$ ) dominates the surface passivation mechanism and also relaxes the requirements on chemical passivation (Fig. 8-b). However,  $J_{0p+}$  is not yet good enough due to a relatively poor chemical passivation after PAFA, which further worsens after firing. By comparison, for the  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  stacks, the excellent post-fired  $J_{0p+}$  is due to an excellent chemical passivation ( $S_n \approx 3650 \text{ cm}\cdot\text{s}^{-1}$ ) combined with a relatively weak negative-charge field-effect passivation ( $Q_{eff} \approx -7.0 \cdot 10^{11} \text{ cm}^{-2}$ ). Thus, an important conclusion in Fig. 8-b is that, although a good level of field-effect ( $Q_{eff}$ ) or chemical passivation ( $S_n$ ) can strongly relax the requirements on the other one, a good emitter passivation still depends on their good combination.

It is also worth stressing that, a  $\text{SiN}_x$  capping layer can only suppress the deterioration degree in chemical passivation of  $\text{Al}_2\text{O}_3/\text{p}^+\text{-Si}$  interface, but it cannot prevent its deterioration. As shown in Fig. 8-a, the post-fired  $S_n$  decreases by a factor of 1.46 (from  $\text{Al}_2\text{O}_3$  to  $\text{Al}_2\text{O}_3/\text{SiN}_x$ ); while  $S_n$  still increases by a factor of 1.2 from after-PAFA  $\text{Al}_2\text{O}_3$  to post-fired  $\text{Al}_2\text{O}_3/\text{SiN}_x$ . Hence, a  $\text{SiN}_x$  capping layer still cannot

effectively improve chemical passivation on its own, but it maintains the passivation mechanism of  $\text{Al}_2\text{O}_3$ . By comparison, the  $\text{SiO}_2$  interlayer significantly improves chemical passivation, as well as changing the passivation mechanism. Overall, the  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  stacks obtained the best post-fired  $J_{0p+}$  due to an excellent combination of chemical and field-effect passivation.

Likewise, a further explanation on Fig. 4 (P emitter) is given by combining with the analysis of Fig. 9. For the  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  stacks (after firing), due to a weak field-effect passivation ( $Q_{eff} \approx -2.1 \cdot 10^{11} \text{ cm}^{-2}$ ), the excellent chemical passivation ( $S_p \approx 1000 \text{ cm} \cdot \text{s}^{-1}$ ) plays a much more important role on the low  $J_{0n+}$ . The emitter passivation mechanism of  $\text{SiO}_2/\text{SiN}_x$  ( $Q_{eff} \approx 2 \cdot 10^{11} \text{ cm}^{-2}$ ,  $S_p \approx 2220 \text{ cm} \cdot \text{s}^{-1}$ ) is similar to  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$ . The  $\text{Al}_2\text{O}_3$  interlayer between  $\text{SiO}_2$  and  $\text{SiN}_x$  can improve the chemical passivation. On the other hand, for the  $\text{Al}_2\text{O}_3/(\text{SiN}_x)$  stacks, the negative  $Q_{eff} = -2.4 \cdot 10^{12} \text{ cm}^{-2}$  still cannot invert the  $\text{n}^+$ -Si surface (Fig. 7-b) and seriously depletes the  $\text{n}^+$ -Si surface, thus resulting in a poor  $J_{0n+}$ . Regarding the improvement in chemical passivation from PAFA to post-firing, the  $\text{Al}_2\text{O}_3/\text{SiN}_x$ ,  $\text{SiO}_2/\text{Al}_2\text{O}_3$ ,  $\text{SiO}_2/\text{SiN}_x$  and  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  stacks decrease  $S_p$  by a factor of 2.3, 2.5, 7.8, 23.4, respectively. Here, a difference from the B emitter is that a  $\text{SiN}_x$  capping layer can effectively improve chemical passivation of  $\text{Al}_2\text{O}_3/\text{n}^+$ -Si interface. Furthermore, the post-fired  $S_p$  decreases by a factor of 4.2 (from  $\text{Al}_2\text{O}_3$  to  $\text{Al}_2\text{O}_3/\text{SiN}_x$ ) and 9.4 (from  $\text{SiO}_2/\text{Al}_2\text{O}_3$  to  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$ ). Overall, the  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  stacks obtained the best post-fired  $J_{0n+}$ .

As mentioned in the introduction, the improved firing stability of  $\text{Al}_2\text{O}_3$  (i.e. the improved chemical passivation of Si interface by a thin  $\text{SiO}_2$  interlayer, or the suppression of deterioration degree in chemical passivation of  $\text{Al}_2\text{O}_3/\text{p}^+$ -Si interface and the improved chemical passivation of  $\text{Al}_2\text{O}_3/\text{n}^+$ -Si interface by a  $\text{SiN}_x$  capping layer) is linked to H passivation provided by  $(\text{SiO}_2)/\text{Al}_2\text{O}_3/(\text{SiN}_x)$  stacks [7, 16, 17, 32–36]. This advantage can be further exploited by utilizing the back-end thermal processes (PECVD  $\text{SiN}_x$ , firing) of screen-printed Si solar cells. Considering the  $Q_{eff}$  tuning effect by the  $\text{SiO}_2$  interlayer,  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  has an excellent chemical passivation combined with a weak field-effect passivation, thus an excellent emitter ( $\text{p}^+$  and  $\text{n}^+$ ) passivation with an outstanding firing stability.

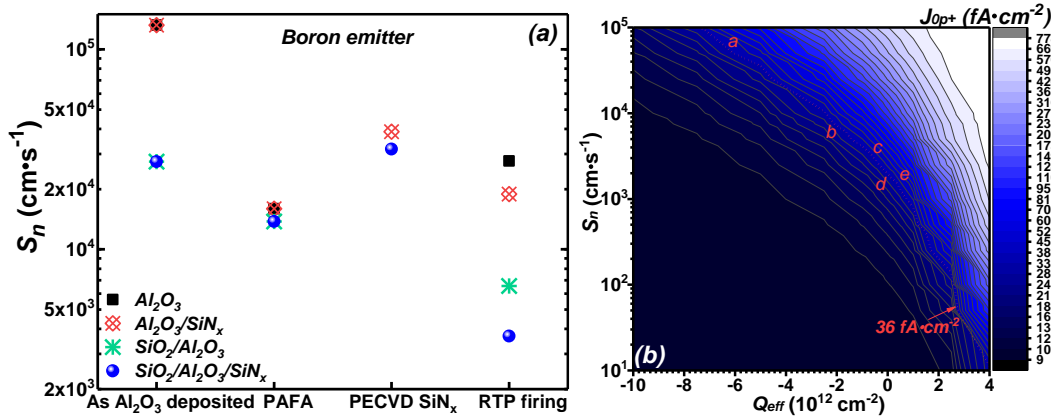

Fig. 8. The PC1D-extracted  $S_n$  as a function of the thermal processes and passivation stacks (a) and PC1D simulated  $J_{0p+}$  contour plot as a function of  $Q_{eff}$  and  $S_n$  (b). 1) B-emitter parameters and  $d_{\text{film}}$  of each layer are shown in Fig. 3; 2) The  $Q_{eff}$  range of  $-1.0 \cdot 10^{13}$  to  $4.0 \cdot 10^{12} \text{ cm}^{-2}$  cannot invert the  $\text{p}^+$ -Si surface in this study (both under dark and 1-sun illumination, see Fig. 7-a); 3) Typical combinations (a, b, c, d, e) of parameters of field-effect and chemical passivation to reach a  $J_{0p+} = 36 \text{ fA} \cdot \text{cm}^{-2}$  are marked (see Sec. 3.2.2).

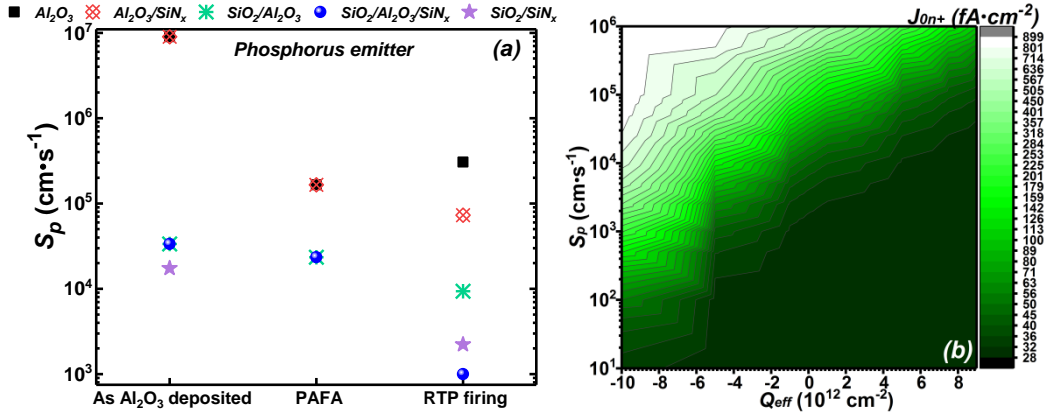

Fig. 9. The PC1D-extracted  $S_p$  as a function of the thermal processes and passivation stacks (a) and PC1D simulated  $J_{0n^+}$  contour plot as a function of  $Q_{\text{eff}}$  and  $S_p$  (b). 1) P-emitter parameters and  $d_{\text{film}}$  of each layer are shown in Fig. 4; 2) The  $Q_{\text{eff}}$  range of  $-1.0 \cdot 10^{13}$  to  $9.0 \cdot 10^{12} \text{ cm}^{-2}$  cannot invert the  $n^+$ -Si surface in this study (both under dark and 1-sun illumination, see Fig. 7-b).

### 3.2.2 Extended discussion on industrial emitter passivation

The same  $J_{0e}$  can be obtained from combinations of different levels of field-effect and chemical passivation, which is linked to different surface passivation mechanisms.  $J_{0p^+} = 36 \text{ fA} \cdot \text{cm}^{-2}$  (the best  $J_{0p^+}$  in Fig. 3) can be achieved with different dielectrics, as shown in Fig. 8-b. For example, with a) plasma ALD  $\text{Al}_2\text{O}_3$  ( $Q_{\text{eff}} \sim -6 \cdot 10^{12} \text{ cm}^{-2}$  [7],  $S_n \approx 6.3 \cdot 10^4 \text{ cm} \cdot \text{s}^{-1}$ ), b) thermal ALD  $\text{Al}_2\text{O}_3$  in this study ( $Q_{\text{eff}} \sim -2.4 \cdot 10^{12} \text{ cm}^{-2}$ ,  $S_n \approx 1.1 \cdot 10^4 \text{ cm} \cdot \text{s}^{-1}$ ), c)  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  in this study ( $Q_{\text{eff}} \sim -7.0 \cdot 10^{11} \text{ cm}^{-2}$ ,  $S_n \approx 3650 \text{ cm} \cdot \text{s}^{-1}$ ), d)  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  with adequate  $d_{\text{SiO}_2}$  (zero  $Q_{\text{eff}}$ ,  $S_n \approx 2200 \text{ cm} \cdot \text{s}^{-1}$ ), or e) PECVD  $\text{SiN}_x$  ( $Q_{\text{eff}} \sim 7.5 \cdot 10^{11} \text{ cm}^{-2}$  [1],  $S_n \approx 1150 \text{ cm} \cdot \text{s}^{-1}$ ). While the above  $S_n$  values have been reached with implanted B-emitters, it is worth to stress that the result of b) is also consistent with diffused B-emitters, e.g. Ma et al [56] obtained  $S_n \approx 1 \cdot 10^4 \text{ cm} \cdot \text{s}^{-1}$  in a similar  $B_{\text{surf}}$  range with PECVD  $\text{Al}_2\text{O}_3/\text{SiN}_x$  stacks ( $Q_{\text{eff}} \sim -2.5 \cdot 10^{12} \text{ cm}^{-2}$ ) using SENTAURUS TCAD simulations.

For industrial surface passivation on only  $n^+$  or  $p^+$  emitter, the preferred choice is to adopt suitable material with an excellent field-effect passivation, e.g.  $\text{Al}_2\text{O}_3$  for  $p^+$  emitter. The PC1D-extracted  $S_n$  ( $S_p$ ) as a function of the  $R_{\square}$  and different stacks (corresponding to Fig. 5) is shown in Fig. 10. It is seen that, although  $\text{Al}_2\text{O}_3/(\text{SiN}_x)$  could well passivate  $p^+$  emitter after PAFA over a broad emitter doping range, its chemical passivation is not yet good and could further worsen after firing despite being partly improved by  $\text{SiN}_x$  capping. Hence,  $\text{Al}_2\text{O}_3$  passivation on  $p^+$ -Si cannot exploit its best potential in screen-printed industrial Si solar cells (see Sec. 3.3) unless chemical passivation can be sufficiently improved. A potential solution is to implement H passivation treatment (hydrogenation) [57–60]. Hydrogenation can be realized by placing wafers into a tool which provides H source, while simultaneously heating and illuminating wafers to accumulate sufficient energy for hydrogenation from the incident photons. It can passivate Si interfaces (dangling bonds or other defects) and Si bulk (crystallographic defects, B-O defects or contamination) based on different mechanisms, and can be applied to both single and multi c-Si (n or p type) solar cells. Here, for its application to  $\text{Al}_2\text{O}_3/(\text{SiN}_x)$  passivation on  $p^+$ -Si, the hydrogenation treatment can be implemented after completion of cell fabrication to improve chemical passivation of Si interface as well as maintaining the strong negative-charge field-effect passivation, thus best exploiting the potential of  $\text{Al}_2\text{O}_3$  passivation. Moreover, the H presented in  $\text{Al}_2\text{O}_3/\text{SiN}_x$  can also be utilized as H source. It is feasible to develop cost-effective and commercial prototypes (tools) to realize such hydrogenation process.

On the other hand, for solar cells with the  $p^+$  emitter and  $n^+$  BSF both placed at the cell rear (e.g. IBC), dielectrics with an excellent chemical passivation and a weak field-effect passivation ( $Q_{eff}$ -range:  $-1 \cdot 10^{11}$  to  $1 \cdot 10^{11} \text{ cm}^{-2}$ ) are the preferred choice, e.g.  $\text{SiO}_2/(\text{Al}_2\text{O}_3)/\text{SiN}_x$ . Emitters with lower  $N_{\text{surf}}$  are more easily suffering from depleted and inverter layers (Fig. 7), and thus relatively more sensitive to field-effect passivation. Thereby, the excellent chemical passivation of  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  can greatly decrease the dependence on field-effect passivation, and it can thus effectively passivate both  $p^+$  and  $n^+$  emitters over a broad emitter doping range (Fig. 5). With increasing  $R_{\square}$  in the ranges in Fig. 10, the  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  stacks (after firing) have  $S_n$  (B emitter) decreasing from  $5.7 \cdot 10^3$  to  $1.9 \cdot 10^3 \text{ cm} \cdot \text{s}^{-1}$ , and  $S_p$  (P emitter) decreasing from  $5.5 \cdot 10^3$  to  $1 \cdot 10^3 \text{ cm} \cdot \text{s}^{-1}$ .

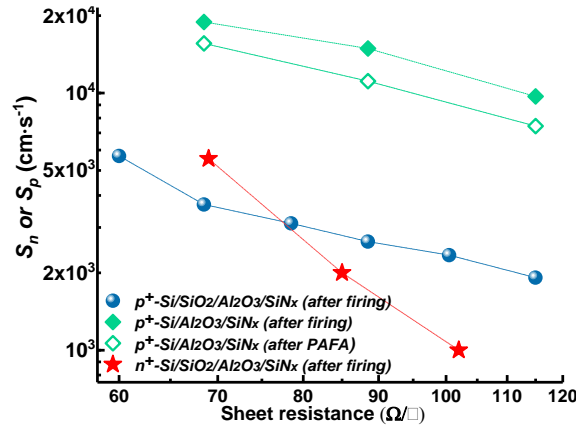

Fig. 10. The PC1D-extracted  $S_n$  ( $S_p$ ) as a function of the  $R_{\square}$  in different stacks. The active  $N_{\text{surf}}$  as a function of  $R_{\square}$  is given in Fig. 5-b.  $d_{\text{film}}$  of each layer is shown in Fig.s 3-4.

### 3.3 Cell performance of p-PERT bifacial cells using $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$ emitter passivation

Based on the results of  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  passivation of B and P emitters, we developed an industrial process (flow in Fig. 2-b) for p-PERT bifacial cells. Fig. 11 shows the front or rear side performance (under front or rear illumination only) of the cells fabricated in the industrial pilot line, which are well consistent with the  $J_{0e}$  results. The details on the groups in Fig. 11 are reported in Table 1. The better cell performance of group C<sub>2</sub> compared to group C<sub>1</sub> (for rear planar cells,  $\Delta V_{oc} \approx 3-4 \text{ mV} - V_{oc}$ , open circuit voltage,  $\Delta \eta \approx 0.25\% - 0.3\%$  -  $\eta$ , cell efficiency) confirmed the better final passivation on  $p^+$  emitter with  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  than with  $\text{Al}_2\text{O}_3/\text{SiN}_x$ . Similarly, the slightly better cell performance of group C<sub>3</sub> compared to group C<sub>2</sub> confirmed the slightly better final passivation on  $n^+$  emitter with  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  than with  $\text{SiO}_2/\text{SiN}_x$ .

In bifacial cells, it is necessary to evaluate both front and rear side performance, which can be quantified via the bifaciality factor  $BF$  ( $BF = \eta_{\text{rear}}/\eta_{\text{front}}$ ), measured under standard test conditions [44]. As shown in Fig. 11, the front side performance of rear planar cells has a clear gain over rear textured cells ( $\Delta V_{oc} \approx 3-4 \text{ mV}$ ,  $\Delta \eta \approx 0.3-0.4\%$ ). This is due to better  $p^+$ -BSF and rear dielectric passivation, as well as better light trapping effect provided by the planar Si (100) surface [61]. On the other hand, the rear side performance of rear textured cells has significant advantage over rear planar cells (especially short circuit current  $J_{sc}$ ) due to receiving more sunlight from the rear with lower reflectance. Overall, the cells demonstrated  $\eta_{\text{front}} \approx 20.0-20.5\%$  and  $\eta_{\text{rear}} \approx 16.9-17.5\%$  for rear planar cells and  $\eta_{\text{rear}} \approx 19.0-19.8\%$  for rear textured cells. Thus, the  $BF$  of the rear planar and rear textured cells are  $\sim 0.85$  and  $\sim 0.98$ , respectively, with rear textured bifacial cells being more cost-efficient in actual environments.

The cell results also confirmed the effective emitter ( $p^+$  and  $n^+$ ) passivation using  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  stacks. Based on our study, the substrate conductivity type is not critical for PERT bifacial cells since good cell performance can be achieved on both p and n substrates with a long enough bulk minority carrier diffusion length. It is worth stressing that, the cells with bifacial  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  passivation on both  $p^+$  and  $n^+$  emitter (group  $C_3$ ) achieved the best performance ( $V_{oc}=657$  mV,  $\eta_{front}=20.5\%$ ,  $\eta_{rear}=19.8\%$ ,  $BF\approx 0.98$ ). Due to the unique feature of bifacial  $\text{Al}_2\text{O}_3$  deposition on Si substrates using ALD process and the combination with fully ion-implanted doping process, the cell process is clearly simplified. Better cell performance can be expected with further optimization of the front  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  ARC layer and the specific Ag and Ag/Al pastes. In summary, the cell results demonstrate that  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  is a promising candidate for industrial emitter passivation.

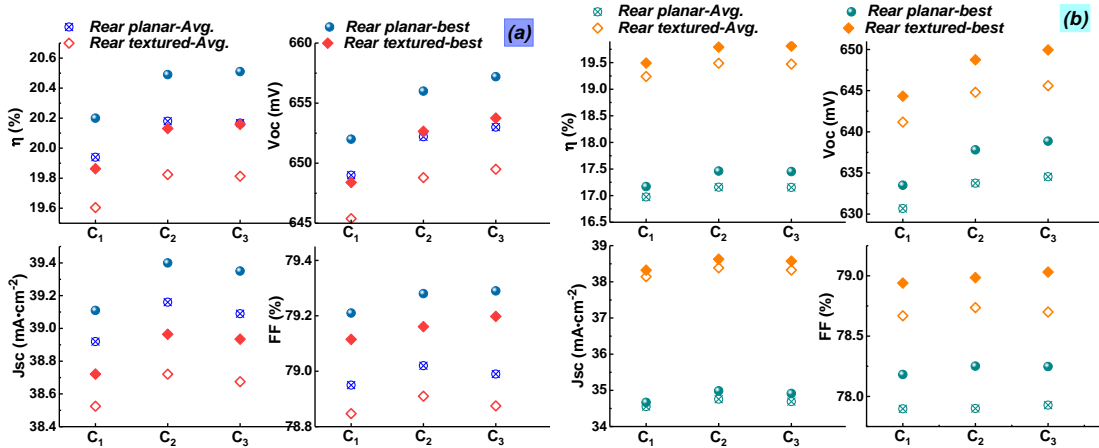

Fig. 11. Front (a) and rear (b) side performance of the industrial p-PERT bifacial cells (rear planar or textured surface) with different passivation stacks using the cell process in Fig. 2-b. Group information is given in Table 1.

Table 1. The group information in Fig. 11. The thicker  $d_{\text{SiO}_2}$  of the front textured (111) Si surface compared to the rear planar (100) Si surface is due to a faster oxidation rate on the (111) Si compared to (100) Si.

Group	Front dielectrics	Rear dielectrics	Rear surface
$C_1$	10 nm $\text{SiO}_2/67$ nm $\text{SiN}_x$	10 nm $\text{Al}_2\text{O}_3/70$ nm $\text{SiN}_x$	planar or textured
$C_2$	10 nm $\text{SiO}_2/67$ nm $\text{SiN}_x$	7 nm $\text{SiO}_2/10$ nm $\text{Al}_2\text{O}_3/70$ nm $\text{SiN}_x$	
$C_3$	7 nm $\text{SiO}_2/5$ nm $\text{Al}_2\text{O}_3/60$ nm $\text{SiN}_x$	5 nm $\text{SiO}_2/5$ nm $\text{Al}_2\text{O}_3/70$ nm $\text{SiN}_x$	

#### 4. Conclusion

In this paper, we have presented an emitter passivation scheme using  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  stacks which can effectively passivate both  $p^+$  and  $n^+$  emitters. We systematically study the emitter passivation mechanisms of  $\text{SiO}_2/\text{Al}_2\text{O}_3/(\text{SiN}_x)$  and  $\text{Al}_2\text{O}_3/(\text{SiN}_x)$  stacks by characterizing the changes in both field-effect and chemical passivation due to different thermal processes, as well as the comprehensive effect of field-effect and chemical passivation on the overall emitter passivation ( $J_{0e}$ ). We have shown that, after a full negative-charge activation by post- $\text{Al}_2\text{O}_3$  furnace anneal, the field-effect passivation of  $(\text{SiO}_2)/\text{Al}_2\text{O}_3/(\text{SiN}_x)$  is nearly unchanged in the subsequent PECVD  $\text{SiN}_x$  and firing processes. The changes in  $J_{0e}$  are mainly due to the changes in chemical passivation. After firing,  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  stacks had an excellent chemical passivation combined with a weak negative-charge field-effect passivation ( $Q_{eff}=-7.0\cdot 10^{11}$   $\text{cm}^{-2}$  for  $p^+$ -Si,  $Q_{eff}=-2.1\cdot 10^{11}$   $\text{cm}^{-2}$  for  $n^+$ -Si); while  $\text{Al}_2\text{O}_3/\text{SiN}_x$  stacks had a strong negative-charge field-effect passivation ( $Q_{eff}=-2.4\cdot 10^{12}$   $\text{cm}^{-2}$ ) combined with a poor chemical passivation. Furthermore, for  $(\text{SiO}_2)/\text{Al}_2\text{O}_3/(\text{SiN}_x)$  passivation on  $p^+$  and  $n^+$  emitter, the  $\text{SiO}_2$  interlayer can effectively improve chemical passivation of Si interface. By comparison, the  $\text{SiN}_x$  capping layer cannot prevent the

deterioration in chemical passivation of  $\text{Al}_2\text{O}_3/\text{p}^+\text{-Si}$  interface, but only suppressing its deterioration degree; while the  $\text{SiN}_x$  capping layer improves chemical passivation of  $\text{Al}_2\text{O}_3/\text{n}^+\text{-Si}$  interface. In addition, the excellent post-fired chemical passivation of  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  due to hydrogen passivation can be further exploited by utilizing the back-end thermal processes of industrial screen-printed Si solar cells. Overall,  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  can well passivate both  $\text{p}^+$  and  $\text{n}^+$  emitter over a broad emitter-doping range, as demonstrated by post-fired  $J_{0\text{p}^+} = 20\text{-}50 \text{ fA}\cdot\text{cm}^{-2}$  and  $S_n = 1.9\text{-}5.7\cdot 10^3 \text{ cm}\cdot\text{s}^{-1}$  with  $R_{\square\text{B}} (N_{\text{surf}})$ -range of  $115\text{-}60 \text{ }\Omega/\square$  ( $8.8\cdot 10^{18}\text{-}2.2\cdot 10^{19} \text{ cm}^{-3}$ ), and post-fired  $J_{0\text{n}^+} = 30\text{-}50 \text{ fA}\cdot\text{cm}^{-2}$  and  $S_p = 1\cdot 10^3\text{-}5.5\cdot 10^3 \text{ cm}\cdot\text{s}^{-1}$  with  $R_{\square\text{P}} (N_{\text{surf}})$ -range of  $100\text{-}70 \text{ }\Omega/\square$  ( $8.8\cdot 10^{19}\text{-}1.2\cdot 10^{20} \text{ cm}^{-3}$ ), respectively. We also propose that, to best exploit the advantage of  $\text{Al}_2\text{O}_3$  passivation on  $\text{p}^+\text{-Si}$ , a hydrogenation treatment after completion of cell fabrication is a potential solution to improve chemical passivation of Si interface as well as maintaining the strong negative-charge field-effect passivation.

We also apply the above results to the industrial p-PERT bifacial cells and present an industrial roadmap based on  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  emitter passivation combined with fully ion-implanted technology. Using this roadmap, industrial p-PERT bifacial cells have demonstrated good bifacial performance with  $\eta_{\text{front}} = 20.0\text{-}20.5\%$ ,  $\eta_{\text{rear}} = 19.0\text{-}19.8\%$  ( $BF \approx 0.98$ ) for rear textured cells and  $\eta_{\text{rear}} = 16.9\text{-}17.5\%$  ( $BF \approx 0.85$ ) for rear planar cells. The cells with bifacial  $\text{SiO}_2/\text{Al}_2\text{O}_3/\text{SiN}_x$  passivation on both  $\text{p}^+$  and  $\text{n}^+$  emitters have also demonstrated promising cell performance and a simplified cell process.

## Acknowledgment

The research work is based on the China-Finland International R&D Cooperation project “Improved cost-efficiency in crystalline silicon solar cells through Atomic Layer Deposited  $\text{Al}_2\text{O}_3$ ”, funded by MOST and TEKES (Finish Project No. 40843, Chinese Project No. S2013GR0622, 2013.05-2016.05). H Huang wishes to thank Intevac ltd. (especially Weicheng Zhu, Xiaochun Lu and Chunfeng Lu) for their help on using the ENERGi implanters and the optimization of the ion implantation processes in this study. T. P. Pasanen acknowledges the Aalto ELEC Doctoral School and Jenny and Antti Wihuri Foundation for the financial support.
