ABSTRACT

The photovoltaic (PV) industry requires efficient cutting of large single and multi-crystalline (sc- and mc-) silicon (Si) wafers. Historically multi-wire slurry sawing (MWSS) dominated, but the higher productivity of diamond-wire-sawing (DWS) holds promise for decreasing PV costs in the future. While surface texturing of DWS wafers is more complicated than of MWSS wafers, especially in mc-Si wafers, nanotexturing has been shown to overcome this challenge. While the benefit of nanotexturing is thus clearer in mc-Si, a universal nano-texture process that also works on sc-Si would simplify and reduce the investments costs of PV production-lines. In this paper, such a nano-texture process is developed using a metal-assisted chemical etch (MACE) technique. Step-by-step characterization of surface structure and reflectance of the MACE process is used after: 1) wafering, 2) standard acidic texturing etch, 3) silver nanoparticles deposition, and 4) MACE nanotexturing for both sc and mc-Si. The results show that the same MACE process works effectively for both sc-Si and mc-Si wafers. Finally, the nano-textured wafers are processed into PV cells in an industrial process line with conversion efficiencies of 19.4 % and 18.7%, for sc-Si and mc-Si solar cells, respectively.

Keywords: black silicon; black Si solar cell; metal-catalyzed chemical etching; metal-assisted chemical etching; Micro-texture; Nano-texture

1. Introduction

The photovoltaic (PV) industry is made up of over 90% traditional single crystalline (sc) and multi-crystalline (mc) silicon (Si) wafer-based devices. Thus, current PV production requires efficient wafering of large Si ingots. This has historically been done with the now well-established multi-wire slurry sawing (MWSS) technology, which has almost no restrictions on the size of the Si ingots. Additionally, for both MWSS sc-Si and mc-Si wafers, there are also well-established surface texturing processes available. The current industry standards are an alkali-based process for MWSS sc-Si and an acid-based process for MWSS mc-Si, the latter of which relies heavily on the formation of thick saw damage on the mc-Si wafer surface during the MWSS process.

Recently, many advances in wafering technology have been made resulting in technique gaining prominence in industry known as diamond wire sawing (DWS). In comparison to MWSS, DWS has many superior features: i) a relatively much higher wafer cutting efficiency (roughly 2-3 × faster), ii) much less waste of highly purified Si from kerf loss and environmental pollution, and iii) no thick damaged layers on both sides of the wafer. With DWS thinner Si wafers can be made to adapt to the developments of the PV industry and it eliminates the need for expensive slurry and the concomitant handling challenges. DWS also significantly reduces the thickness and the density of saw damage resulting only in shallow saw marks near the surface. From the point-of-view of wafer quality (i.e. minority carrier lifetime), the significantly reduced saw damage is a desired feature. However, this also makes the texturing of DWS wafers much more complicated than MWSS wafers. While the lack of deep and dense saw damage is not an issue in sc-Si wafers that use alkaline texturing, mc-Si texturing using the standard anisotropic acidic micro-texturing process is not applicable as it is known to require deep saw damage to be effective. In addition, due to the difference between the acidic and alkaline micro-texturing processes, the equipment used for sc-Si and mc-Si are different. Thus, a simple and universal process for the texturing independent of the thickness of saw damage layers for DWS-processed sc-Si and mc-Si would be a significant benefit for the PV
industry.

One potential solution to overcome this texturing problem is to fabricate a nanostructure on the wafer surface. This nanostructure is commonly called “black silicon” (b-Si) because of the outstanding ability to enhance light absorption rendering the surface visibly black. High-quality b-Si can be produced by laser texturizing and reactive ion etching (RIE). For example, a b-Si solar cell with interdigitated back-contacts has achieved over 22% efficiency with the use of an appropriate atomic layer deposition (ALD) passivation of a cryogenically deep reactive ion etched black silicon surface. In comparison to such complex techniques, the wet metal-assisted chemical etching (MACE) technique has been studied widely due to its low-cost. Several metals, such as gold (Au), platinum (Pt), silver (Ag) and copper (Cu), have been successfully used in MACE (also called MCCE for metal catalyzed chemical etching). The metal catalysts can be deposited by a number of techniques including sputtering, electrochemical deposition, evaporation and electro-less displacement. MACE-based b-Si nanotexturing has been used e.g. since 2014 in MWSS mc-Si solar cell mass production by Canadian Solar Inc. (CSI) in Suzhou.

There is some initial data indicating that the same nanotexturing methods used for b-Si formation could be effective with both MWSS and DWS mc-Si wafers. In previous studies, Ag was used in a MACE process that resulted in an 18.45%-efficient MWSS mc-Si solar cell and an 18.32%-efficient DWS mc-Si solar cell. However, there has been less intensive investigation of nanotexturing on higher performing sc-Si solar cells. Oh et al. reported an 18.2% efficiency, which is much lower than that of routinely manufactured sc-Si solar cells (where the standard inverted pyramid structure can reduce the reflectance to acceptable levels). Even though sc-Si does not require nano-texture as alkaline works efficiently, a universal process would simplify manufacturing and reduce PV costs. Here the potential of a simple MACE nanotexturing process for both sc-Si and mc-Si DWS wafers is systematically investigated. After each step of 1) wafering, 2) standard acidic micro-texturing etch, 3) Ag nanoparticles deposition and 4) MACE nanotexturing, each type of wafer (DWS sc-Si and mc-Si) is characterized for microstructure and reflectance. Finally, the MACE nano-textured wafers are processed into PV cells and their device performances are measured and reported. The primary novel contribution to this work is to demonstrate a MACE process that works effectively for both sc-Si and mc-Si wafers to make high efficiency Si solar cells.

2. Methods

Figure 1. Experimental procedure.
The complete experimental procedure for this study, including individual processing and characterization steps, is outlined in Fig. 1. Both sc-Si (with crystal orientation (100)) and mc-Si wafers were used in the experiments. The wafers were of the standard 156 × 156 mm² size and the wafering was done by DWS to an initial thickness of 180 μm. Directly after wafering, the surface of the wafers was characterized by SEM (EBL Zeiss Supra 40) and reflectance measurements (UV-Vis-NIR Agilent Cary 5000). Next, a standard isotropic acidic texturing process in a HF/HNO₃ solution was applied. The resulting micro-texture was characterized by SEM and reflectance measurements. Then, the wafers experienced a MACE nanotexturing process. The MACE process consisted of three parts: i) nano-pore formation in a HF (49 wt%): H₂O₂ (28 wt%): AgNO₃ (10 wt%): H₂O = 8 : 1 : 0.018 : 32 solution for 5 min., ii) polishing in a HF (49 wt%): HNO₃ (69 wt%): H₂O = 3 : 50 : 70 solution for 30-180 s, and iii) Ag particle removal in 69% HNO₃ solution for 6 min followed by etching in 4% HF solution and rinsing in de-ionized water, all under room temperature. After the processes, the results were characterized by SEM and reflectance measurements.

To better understand the MACE nanotexturing process and its applicability on DWS wafers, an additional Ag nanoparticle deposition experiment was also performed after the standard acidic texturing. In this extra experiment, Ag nanoparticles were deposited on the wafers in a separate solution containing 0.0003 mol/L AgNO₃ and the immersion time was varied from 1 to 5 min. After the deposition, the distribution of the Ag nanoparticles on the wafer surfaces was characterized by SEM.

Finally, the micro-textured and nano-textured DWS sc-Si and mc-Si wafers were fabricated into solar cells following the standard process at Canadian Solar Inc. (in Suzhou). The solar cells were characterized by internal quantum efficiency (IQE, QEX7 USA) and light current-voltage (IV, Berger PSL-SCD Germany) measurements under AM 1.5G and 1 sun illumination at 25°C.

3. Results and Discussions

3.1 DWS and standard acidic texturing

Figure 2. SEM images of the sample surfaces both directly after the DWS wafering (a) sc-Si and b) mc-Si and after applying a standard acidic micro-texturing process (c) sc-Si and d) mc-Si.

Fig. 2 shows the surface morphologies of the samples both directly after the DWS wafering and after applying a standard acidic micro-texturing process. Fig. 2. a) and b) clearly show that DWS wafers, regardless of either single or multicrystalline Si, have a significant quantity of parallel (relatively minor) saw marks/grooves (~1-3 μm) and disperse pits on the surface. These are the well-known results of DWS process. After the standard acidic micro-texturing process, both sc-Si and mc-Si surfaces have similar initial micro-oval texture of ~2-3 μm in width and ~0.5-1 μm in depth as
shown in Fig. 2 c) and d). This depth can be more easily seen and is quantified in cross-sectional SEMs shown in Fig. 3. Fig. 2 also shows that deeper saw marks have a larger micro-texture size than shallower ones. However, it is also clear that (very) shallow saw marks remain on the surfaces even after micro-texturing for both materials, mainly because of the two different etching speeds between the two kinds of saw marks\(^65\). The saw damage resulting from the DWS process is clearly not enough for a standard anisotropic acidic micro-texturing process to form an acceptable antireflection layer for PV.

![Cross-sectional SEM images of the sample surfaces after applying a standard acidic micro-texturing process a) sc-Si and b) mc-Si.](image)

**Figure 3.** Cross-sectional SEM images of the sample surfaces after applying a standard acidic micro-texturing process a) sc-Si and b) mc-Si.

Fig. 4 shows the reflectance (R) as a function of wavelength (\(\lambda\)) of the same samples as shown in Fig. 2 (i.e. directly after DWS wafering and after standard acidic micro-texturing). As-cut DWS sc-Si and mc-Si wafers have a similar initial reflectance. After the micro-texturing process, the average reflectance (R\(_a\)) of DWS sc-Si and mc-Si wafers can be reduced from 33.6% to 29.0% and 34.1% to 30.3%, respectively. However, it is clear, that the combination of DWS and the standard acidic micro-texturing is not nearly as effective as the normal combination of MWSS sc-Si and an alkali-based process (e.g. R\(_a\) ~ 13.0% in a wavelength range between 350 and 1050 nm)\(^65\) or MWSS mc-Si and an acid-based process (e.g. R\(_a\) ~ 23% in a wavelength range between 300 and 900 nm)\(^66\). In the case of mc-Si wafers, the lack of the thick saw damage here after the DWS process can be considered as the main reason for the significantly higher reflectance. In addition, for sc-Si, the micro-oval texture on the surface resulting from this process has a higher reflectance than the inverted pyramid structure obtainable with the current alkali-based industry standard after the DWS process\(^17\). This is due to the worse surface light-trapping properties because a large part of reflected light strikes the surface only once and then escapes\(^17\). Therefore, the absorption opportunities of a photon passing
through the silicon are reduced.

**Figure 4.** Reflectance curves of sc-Si and mc-Si samples directly after DWS wafering and after standard acidic micro-texturing. The average R values in a wavelength range of 400-1050 nm are also shown.

**3.2 MACE nanotexturing**

**Figure 5.** The surface morphologies of sc-Si (top row) and mc-Si (bottom row) wafers with different polishing times of a) and d) 30 s; b) and e) 90 s; c) and f) 120 s.

Although the MACE technique can reduce the surface reflectance to <5% for a wavelength range of 300-1000 nm, it has been demonstrated that with conventional SiNₓ passivation the surface recombination will be increased due to the increasing surface area. Thus, if novel ALD passivation schemes nullifying this problem are not available, an optimum in the degree of nanotexturing must be found. In other words, a compromise between lowering the reflectance and increasing the surface recombination by nanostructuring has to be made. Here this was accomplished by doing additional polishing after the nano-pore formation. Fig. 5 presents SEM images of the sample surfaces obtained after the MACE nanotexturing process, a), b) and c), and d), e) and f) are taken from the surface of sc-Si and mc-Si wafers with different polishing times of 30 s, 90 s and 120 s, correspondingly. What is interesting to notice from Fig. 4 a-c (for sc-Si) and d-f (for mc-Si) is that with the increasing polishing time, the saw marks on the surface of both sc-Si and mc-Si wafers seem to become progressively fewer and are almost completely removed after 120 s (Fig. 4 c & f). This was not the case after the conventional acidic texturing process (Fig. 2). In addition of nanostructure formation, it seems that on the contrary to mere acidic texturing, the MACE process with additional polishing would be able to also remove the microscopic saw marks and thus flatten out the wafer surface on a microscopic level.

To better understand this result, an additional Ag nanoparticle deposition experiment was also performed on the DWS cut wafers Fig. 6 a), b) and c), and d), e) and f) are taken from the sc-Si and mc-Si wafer surfaces after a separate Ag nanoparticle deposition of a varying time of 60 s, 180 s and 300 s, correspondingly. The molar concentration of Ag ions used is approximately equal to that in the MACE process used here. Fig. 6 reveals that the Ag nanoparticles prefer to deposit around the saw marks rather than on the flat areas. Therefore, there are more nano-pores formed in the area of the saw marks. The denser Ag nanoparticle deposition likely results from an increased amount of crystal defects distributed around those areas. As a result, the dense nano-texture is then more easily etched in the MACE polishing step resulting in the removal of the saw marks and the flattening of the wafer surface on a microscopic level.
Figure 6. The distribution of Ag nanoparticles on the sc-Si (top row) and mc-Si (bottom row) wafer surfaces with different deposition times, a) and d) 60 s, b) and e) 180 s, c) and f) 300 s.

The final nano-textures of sc-Si and mc-Si were fabricated with 180 s and 150 s polishing times correspondingly and the resulting reflectivity versus wavelength curves in the wavelength range of 400-1050 nm after the MACE process are shown in Fig. 7. It also compares the different nano-textures for sc-Si and mc-Si. By increasing the polishing time, the nano-texture with wider diameter (~950 nm) and shallower depth (~400 nm) is obtained on the surface of the sc-Si wafer, which is different from the nano-texture obtained on the mc-Si wafer (~720 nm in width and ~430 nm in depth). In this case, after the complete MACE process, the reflectivity of DWS sc-Si and mc-Si wafers can be controlled down to 13.2% and 18.4%, respectively. The achieved reflectance of mc-Si is much lower than the conventional acid-based texturing. The results here are on a similar level as in previous work (~18.21% in a wavelength range of 300-1200 nm), which has been proven to provide a good cell efficiency.55 However, here the fabricated nano-texture is dissimilar to the previous one that has a shallower depth (~360 nm), but a narrower diameter (~430 nm). This indicates that both kinds of nano-texture have a roughly equivalent ability to control light absorption in Si. For sc-Si, due to the superiority of crystal nature, the reflectivity is lower than that of mc-Si here, even if a longer polishing time was used in sc-Si. In addition, this kind of nano-texture of sc-Si has less surface area than mc-Si and the reflectance is comparable to that of the alkali texturing process with tetramethylammonium hydroxide (TMAH) pre-polishing (~13.1% in a wavelength range of 350-1050 nm).65
Figure 7. Reflectance of nano-textured DWS sc-Si and mc-Si wafers after the MACE process with different optimized polishing step times (i.e. 180 s for sc-Si and 150 s for mc-Si). The average R values in a wavelength range of 400-1050 nm are also shown. Inset: The cross-sectional SEM images of the sc-Si at 180 s and mc-Si at 150 s.

3.3 Solar cell results

The preliminary optimization of the DWS sc-solar cells is summarized in Table 1 for polishing times of 120, 150 and 180 seconds. There may be potential to further increase the FF and efficiency by more carefully optimizing the polishing time, but this is left for future work.

Fig. 8 shows the internal quantum efficiency (IQE) (ratio of the electrons collected per absorbed photons) of nano-textured DWS sc-Si and mc-Si solar cells. The average IQE values in the range of 400-1050 nm are 94.24 % and 92.06 %, respectively. A clear deviation is observed in the wavelength range from 400 nm to 950 nm, which is primarily the region of visible spectrum. It appears that the higher IQE value of sc-Si implies a lower surface recombination due to the lower density of defects, which mainly results from the comparatively flat surface situation generated by increasing the polishing time. In addition, Park et al. reported that the surface morphologies have influence on the shape of the emitter layer. In the case of sc-Si, a larger nano-texture may allow a more homogeneous emitter layer formed during phosphorous diffusion, which will also make a contribution to the
improvement of IQE than that of mc-Si. For sc-Si, IQE is only slightly lower than 94.49 % obtained in the previous work. Thus, the nano-textured sc-Si solar cells could still have a bit more potential in the short wavelengths that could be realized by modifying the structure further, although, compared with Oh et al., some progress is made here in this wavelength range at the cost of reflectance. In addition, the value of mc-Si is at same level with 92.24 % obtained in previous work.

**Figure 8.** IQE curves of nano-textured DWS sc-Si and mc-Si solar cells. The average IQE values in a wavelength range of 400-1050 nm are shown in the legend.

The IV-characteristics of the microtextured reference sc-Si and mc-Si solar cells and the MACE nano-textured sc-Si and mc-Si solar cells are shown in Table 2. The micro-textured DWS sc-Si and mc-Si reference solar cells have a similar limited efficiency of about 18.2 %. As stated earlier, the DWS process does not result in thick enough saw damage for the conventional acid-based texturing to work properly. Therefore, the reference cells suffer from poor reflectance resulting in lower light absorption and lower short-circuit current ($I_{sc}$). In addition, the saw marks remaining on the wafer surface after microtexturing can also lead to non-uniformity of the p-n junction and to a higher series resistance ($R_s$) if the Ag fingers cross these grooves.

Reflectance reduction and the surface morphology modification with MACE nanotexturing results in significant improvements. After nanotexturing, the efficiencies of the best nano-textured DWS sc-Si and mc-Si cells can reach 19.38% and 18.72 %, respectively. Both $I_{sc}$ values of nano-textured sc-Si and mc-Si cells are improved and $R_s$ values are also reduced. The $I_{sc}$ improvements can be mostly directly
linked to the lower reflectance. However, the reduced $R_s$ values also play a role. Interestingly it seems that the removal of the microscopic saw marks has a positive effect on the $R_s$ values. This is in accordance with earlier results where a pretreatment removing the saw marks of DWS wafers was seen to have a positive effect on $R_s$. On the other hand, the introduction of nanoscale texture could result in a relevant poor contact between electrode and wafer compared with micro-textured Si solar cells, which will lead to the reduced shunt resistance ($R_{sh}$) for nano-textured Si solar cells. However, a larger nano-texture in the sc-Si surface should make the p-n junction and the Ag fingers more uniform and result in the lower $R_s$ and higher $R_{sh}$ than that of mc-Si. More importantly, because of the preliminary optimization of the nano-texture by polishing, there is no obvious decrease observed in the open-circuit voltage ($V_{oc}$) for sc-Si and mc-Si.

Overall, the results of this study are promising, as they have shown that MACE formation of nano-texture is an effective method to achieve high efficiencies of DWS for both sc-Si and mc-Si. However, MACE-based black silicon PV do not have as high of performances as dry etched black silicon PV, and future work is necessary to further refine the MACE process to develop more optimal microstructures. For example, as seen in the SEM images above, after polishing and flattening the surface, there is no longer any micro-textures on the surface. Thus, future experiments could determine if the micro-texturing step might be skipped before MACE process. In addition, the highest performing black silicon devices are passivated with atomic layer deposition, which should be used to improve the performance of MACE-processed PV devices even higher. With these technical advancements there is the potential for MACE-processed black silicon to compete with the promise of dry-etched black silicon solar cells.

4. Conclusions

This study has shown that this universal nanotexturing process is an effective method to overcome the lack of deep saw marks from the DWS process and create excellent light trapping structures for both sc-Si and mc-Si. Systematic characterization during the steps of the MACE process revealed the impact of nanotexturing on both types of materials. The solar energy conversion efficiency of the nano-textured DWS sc-Si and mc-Si photovoltaic cells reached the level ~19.4% and ~18.7%, respectively. The results demonstrated that such a universal nanotexturing process has significant potential to enable high performance DWS Si wafers of either sc or mc type, thus simplifying production lines and further reducing production costs for the entire PV industry.
