**Abstract:** In this work, technological feasibility of autonomous corrosion assessment of reinforced concrete structures is studied. Corrosion of reinforcement bars (rebar), induced by carbonation or chloride penetration, is one of the leading causes for deterioration of concrete structures throughout the globe. Continuous nondestructive in-service monitoring of carbonation through pH and chloride ion ( $\text{Cl}^-$ ) concentration in concrete is indispensable for early detection of corrosion and making appropriate decisions, which ultimately make the lifecycle management of RC structures optimal from resources and safety perspectives. Critical state-of-the-art review of pH and  $\text{Cl}^-$  sensors revealed that the majority of the sensors have high sensitivity, reliability, and stability in concrete environment, though the experiments were carried out for relatively short periods. Among the reviewed works, only three attempted to monitor  $\text{Cl}^-$  wirelessly, albeit over a very short range. As part of the feasibility study, this work recommends the use of internet of things (IoT) and machine learning for autonomous corrosion condition assessment of RC structures.

**Keywords:** sensors; internet of things; intelligent data analytics; machine learning; deep learning; autonomous corrosion assessment; corrosion; reinforced concrete

## 1. Introduction

Reinforced concrete (RC) structures represent a large proportion of the world's physical infrastructure with great economic importance. Building and infrastructure accounts for 47% of the world gross domestic product [1]. Despite their contribution to the economy, a high number of infrastructure in industrialized countries are approaching the end of their service life and suffer from considerable degree of deterioration [2,3]. For example, the US physical infrastructure is graded as D<sup>+</sup> (one scale above from the least grade) by American Society of Civil Engineers in 2017, indicating that the infrastructure is generally at risk [4].

Corrosion of reinforcement bars (rebar) is one of the major causes for degeneration of RC structures throughout the world, especially those exposed to aggressive environments [5–7]. Studies have demonstrated that corrosion of rebar has already reached an alarming level and the associated maintenance and repair costs exceed multibillion USD per year globally. In the developed countries corrosion cost is estimated in the range of 3.5–4.5% of their GDP [8]. Continued rebar corrosion in repaired RC structures is even responsible for 37% of the failure modes [9], causing costly repairs [9–11].

Naturally, concrete cover provides a high level of protection to the embedded rebar against corrosion since the pore solution of the concrete is alkaline with a pH of 12–13. Under this amount of alkalinity, rebar persists passivated. However, the passivation of rebar is breakdown due to the presence of  $\text{Cl}^-$  or by the carbonation of the concrete [12–14]. Carbonation is a natural physicochemical process triggered by the penetration of  $\text{CO}_2$  from the neighboring environment into the concrete through pores in the matrix where the  $\text{CO}_2$  reacts with hydrated cement [15,16]. Although the reduction of alkalinity

caused by carbonation changes the chemical composition of concrete, its major out-turn is that it destroys the passive oxide layer of rebar, which eventually initiates corrosion [13,15,17–19]. The penetration of  $\text{Cl}^-$  is also the primary cause for rebar corrosion in concrete environment. Like carbonation, the penetration of  $\text{Cl}^-$  does not typically cause harm directly to the concrete. Nonetheless, when the amount of  $\text{Cl}^-$  concentration at the rebar reaches a certain threshold, depassivation occurs that cause corrosion initiation [20–24]. Indeed, the chloride threshold levels are considerably scattered over a wide range of values (from close to zero to about 2.5 wt%  $\text{Cl}^-$  by mass of binder) as it is controlled by several factors including composition of the concrete, the type of rebar, and the exposure conditions [25,26]. Both, carbonation- and chloride-induced corrosion, dwindle the cross-sectional area and the resistance of the rebar. This causes severe cracking as well as reduction in the load-bearing capacity of the infrastructure. Cracked concrete allows an additional entry of moisture, aggressive gasses, and ions, aggravating rebar corrosion and concrete degradation. Subsequently, the serviceability, strength, and safety of the infrastructure are impacted adversely.

Corrosion initiation time must be precisely estimated to carry out in-time and cost-effective maintenance decisions to prevent RC structures from corrosion-induced damage. To do so, continuous assessment of pH of the concrete and the amount of  $\text{Cl}^-$  concentrations in the concrete is crucial. Measurement of pH of the concrete can indicate the risk of corrosion caused by carbonation. The conventional methods for evaluating carbonation and the  $\text{Cl}^-$  content in concrete is often semi-destructive, time-consuming, and demand periodic repetition [27]. In these methods, the depth of carbonation and the amount of  $\text{Cl}^-$  concentrations in the concrete are determined using chemical and/or physical laboratory tests of samples taken from in-service structures. Due to these facts, the conventional techniques cannot be applied for frequent measurements. In addition, performance investigation of RC structure either in the field or laboratory (by taking sample from the structure) usually incur a high amount of direct and indirect costs [28]. For instance, traffic delay costs caused by conventional field inspection and maintenance programmes are valued to be in the range of 15–40% of the construction costs [29]. After evaluating the carbonation front and the amount of chloride concentration from the samples, prediction of the remaining lifetime of the structure is usually carried out using conventional empirical models. These models are based on Fick's second law of diffusion and comprises several assumptions and simplifications, inducing considerable uncertainty in predicting the time to onset rebar corrosion [30]. This uncertainty could have serious effect on inspection and maintenance planning, which in turn adversely influence the service life of the structure and escalate the life-cycle costs. Therefore, reliable, cost-effective, and in-service monitoring of pH and  $\text{Cl}^-$  concentration in concrete along with accurate corrosion assessment method is indispensable, which ultimately makes the service-life management of RC structures efficient from economy and safety perspectives.

The objective of this work is to carry out feasibility study on autonomous assessment of rebar corrosion due to carbonation and  $\text{Cl}^-$  penetration in RC structures. The contributions of this work are threefold: (i) in-depth review of state-of-the-art  $\text{Cl}^-$  and pH sensing devices that can be embedded in concrete structures, (ii) study on the potential of IoT system for continuous  $\text{Cl}^-$  and pH monitoring, and (iii) a critical insight into the integration of IoT systems and intelligent data analytics to achieve autonomous corrosion assessment of RC structures.

The structure of the remainder of the paper is as follows. In Section 2, various types of sensing devices that are proposed for monitoring  $\text{Cl}^-$  and pH in concrete environment are critically reviewed. The possibility of integrating the physical infrastructure with digital technologies by employing internet of things based continuous  $\text{Cl}^-$  and pH monitoring system is presented in Section 3. In Section 4, the future smart infrastructure that autonomously assess the corrosion condition of RC structures is proposed. Finally, conclusions are provided in Section 5.

## 2. State-of-the-Art Chloride and pH Sensors

The risk of structural disintegration of infrastructure caused by rebar corrosion fosters the development of sensing devices for continuous nondestructive monitoring that enable early detection of corrosion. Over the past years, embeddable sensors have been developed and installed in concrete structures for monitoring the corrosion state of rebar. There are even commercially available corrosion monitoring systems based on different approach including measurements of macrocell, resistivity, and electrochemical polarization dynamics. The drawback of these types of sensors is that they provide information about the corrosion state of the rebar after corrosion has initiated. While sensors that can monitor pH of the pore solution and  $\text{Cl}^-$  concentration can deliver information about the state of the rebar embedded in the concrete well before corrosion initiates, serving as early alerting systems. Hence, this paper focuses in reviewing only  $\text{Cl}^-$  and pH sensors that monitor chloride concentration and pH of the concrete pore solution. In addition, pH and  $\text{Cl}^-$  sensors can be used for controlling concrete repair works. For example, repair work to passivate rebar using electrochemical chloride extraction and re-alkalization methods [31].

To perform a thorough study on the recent development of  $\text{Cl}^-$  and pH sensing devices that can be embedded in concrete structures, databases of the Scopus and Web of Science were selected for analysis. Both are abstract and citation databases of peer-reviewed literature, delivering a complete citation search by giving access to numerous databases. A set of queries that comprise the manuscript's title, topic, abstract, and keywords were carried out on every database in order to choose works reporting  $\text{Cl}^-$  and pH sensing devices that can be embedded in concrete structure. Since one of the focuses is to evaluate the current development  $\text{Cl}^-$  and pH sensors, the lifespan of the search criteria for both databases were set to 10 years. Any duplicated records from the databases were removed and then manually checked to select suitable ones. Table 1 presents the applied search terms, selection criteria and number of records screened and included. A total of 34 scientific papers have been critically reviewed and presented the findings. As can be seen in Table 1, more number of chloride sensors have been proposed compared to pH sensors.

### 2.1. Potentiometric Sensors

In the past few decades, several electrochemical sensors based on potentiometric ion-selective electrodes (ISEs) have been developed to monitor change of  $\text{Cl}^-$  concentrations in concrete. ISEs are firmly established and have been adopted in several areas. For instance, in the area of analytical chemistry, ionic activity of some specific species had been examined using a potential measurement [32]. The working principle of potentiometric sensors is based on potential change caused by the chemical activity of the sensed ion with regard to a reference ISE under the conditions of no current flow.

Typically, such types of electrodes are primarily membrane-based devices, comprising ion-conducting permeable materials, which isolate the sample from the inside of the electrode [33]. One of the electrodes is the working or indicator electrode whose potential is determined by its environment. The second electrode is a counter or reference electrode which has a fixed potential. Since the potential of the counter electrode is constant, the potential difference value can be associated with the dissolved ion concentration [33].

The potential of a potentiometric sensor is estimated using the Nernst equation, described by Equation (1) [24], which determines the linear dependence of the sensor response ( $E$ ) on the logarithm activity change of the ion in the solution:

$$E = E^0 + \frac{RT}{nF} \ln[a_{Cl^-}] - E_{ref} \quad (1)$$

where  $E$  is the potential difference for the electrochemical cell composed of the ion-selective and reference electrode [V],  $E^0$  is the standard electrode potential,  $R$  is the gas constant [ $J \text{ mol}^{-1} \text{ K}^{-1}$ ],  $T$  is the absolute temperature [K],  $F$  is the Faraday constant [ $C \text{ mol}^{-1}$ ],  $n$  is the number of electrons involved in the reaction, and  $a_{Cl^-}$  is the chemical activity of the  $Cl^-$  [ $\text{mol dm}^{-3}$ ], and  $E_{ref}$  is the standard reference electrode potential [V].

The widely used reference electrodes and their potentials with respect to the regular hydrogen electrode (NHE) is given in Table 2. It can be noticed that the unpolarizable reference electrodes (calomel ( $\text{Hg}_2\text{Cl}_2$ ), silver/silver chloride ( $\text{Ag}/\text{AgCl}$ ), manganese dioxide ( $\text{MnO}_2$ ), copper/copper sulphate ( $\text{Cu}/\text{CuSO}_4$ )) have constant potential values. All the polarizable electrodes, except lead (Pb), showed potential values with a fluctuation range of  $\pm 20$  [34,35]. Among all,  $\text{Ag}/\text{AgCl}$  are the most widely used electrodes for measurement of different environments, including concrete [36,37]. This is due to the fact that these electrodes have the following superior characteristics: (i) exhibit potential regulated by a reversible balance, (ii) return to the reversible potential after small polarizations, and (iii) stable and robust [37].

**Table 2.** Characteristics of commonly applied reference electrodes with their potentials versus NHE, adopted from [34].

Electrode	Type	Potential (mV vs. NHE)	Typical Configuration
Calomel	Unpolarizable	+244	Mercury chloride ( $\text{Hg}_2\text{Cl}_2$ ) paste on mercury (Hg) and a base metal rod (Pt) in a solution of potassium chloride (KCl).
Copper/copper sulphate		+316	Copper rod surrounded by a saturated solution of copper sulphate.
Silver/silver chloride		+199	Silver rod in silver chloride paste in a saturated solution or 0.5 M KCl solution.
Manganese dioxide		+365	Manganese dioxide paste on a base material (graphite) in 0.5 M potassium hydroxide (KOH) solution with a cementitious plug as contact to the concrete.
Graphite	Polarizable	$+150 \pm 20$	Delivered with an isolating jacket leaving the tip exposed.
Activated titanium		$+150 \pm 20$	
Stainless steel		$+150 \pm 20$	
Lead		$-450$	

### 2.1.1. Potentiometric Chloride Ion Sensors

Though the fundamental principles of potentiometric ISEs based sensors are well established and widely applied in the field of electrochemistry, their applicability in concrete must be assessed. Sensors that can be mounted in concrete should operate in high alkaline environment and in a wide range of  $Cl^-$  concentrations for a long time while providing accurate and reliable results. Moreover, the stability of the  $Cl^-$  sensors to pH changes and other major interfering ions (which come from the

environment and/or the concrete ingredients) should be assured. There are studies that have evaluated the performance of potentiometric ISEs in monitoring  $\text{Cl}^-$  concentration in concrete [32,38–48].

Ag/AgCl electrodes are the most commonly utilized and commercially available chloride ion selective electrodes [27,43]. It comprises a wire made of silver (Ag) coated with a conversion layer of silver chloride (AgCl). The first attempt to measure activities of  $\text{Cl}^-$  using Ag/AgCl electrodes in hardened mortar was documented in the early 1990s [5]. Since then, several  $\text{Cl}^-$  sensors based on Ag/AgCl electrodes have been developed. Table 3 summarizes the development progress of state-of-the-art  $\text{Cl}^-$  and pH potentiometric sensors and their performance in concrete environment. The performance of the sensors was evaluated using simulated concrete pore solutions, mortar, and concrete.

Femenias et al. [44] investigated the sensitivity of the Ag/AgCl electrodes to other interfering species that can be emanating from the surrounding environment and/or from the concrete mix ingredients. The findings of the investigation demonstrated that insignificant interference from fluoride, sulphate, and hydroxyl but substantial from bromide and sulphide. In completely chloride-free alkaline solutions, the ISEs were not stable over time, but upon arrival of  $\text{Cl}^-$ , it reliably measures the  $\text{Cl}^-$  concentration. The authors concluded that Ag/AgCl electrode can satisfactorily be applied to monitor the amount of  $\text{Cl}^-$  in RC structures exposed to chloride-laden environments. Montemor et al. [38] evaluated the suitability of Ag/AgCl electrodes for in-service monitoring of  $\text{Cl}^-$  in concrete environment. The evaluation was performed in mortar and concrete specimens at different depths by exposing to a broad range of  $\text{Cl}^-$  concentrations. The reported results revealed that the Ag/AgCl based chloride sensor is reasonably stable.

Pargar et al. [41] characterized the response of Ag/AgCl in simulated pore solutions by testing with variable amount of  $\text{Cl}^-$  and pH values. The claimed test results showed that the influence of pH on the potential value of the sensor is trivial at  $\text{Cl}^-$  concentrations of  $>4$  mM. This makes Ag/AgCl based sensors are practical to monitor the change of  $\text{Cl}^-$  in concrete structures since  $\text{Cl}^-$  concentration of 4 mM is much under than the usually stated thresholds that initiate rebar corrosion in concrete. As the pH has a notable effect on the reading of the sensor at low  $\text{Cl}^-$  concentration ( $<4$  mM), it is vital to monitor the pH value and  $\text{Cl}^-$  concentration simultaneously for accurate measurement of  $\text{Cl}^-$  content. Similar phenomenon was also observed regarding the influence of pH on measuring  $\text{Cl}^-$  concentration in concrete made by another study [32]. Jin et al. [43] applied Ag/AgCl based sensors to monitor  $\text{Cl}^-$  concentration in concrete specimens composed of different mineral admixtures at different depths. On the basis of the potential analysis of the embedded  $\text{Cl}^-$  sensor, the authors concluded that continuous monitoring of  $\text{Cl}^-$  concentration in RC structure could be achieved. They also remarked that extra efforts are required to produce inexpensive, robust, and reliable  $\text{Cl}^-$  potentiometric sensors that can be utilized in concrete environment.

Karthick et al. [45] produce a solid-state alkaline stable polymer-coated Ag/AgCl sensor for monitoring of  $\text{Cl}^-$  concentration in concrete structure. The alkaline stability of the sensor and the coating material were evaluated in synthetic concrete pore solution and characterized using advanced tests, including half-cell potential, scanning electron microscopy (SEM), X-ray diffraction (XRD). The sensor was calibrated in wide range of  $\text{Cl}^-$  concentrations using three different solutions: (i) saturated KCl solution, (ii) distilled water solution, and (iii) synthetic concrete pore solution. Then the sensor was embedded in the concrete at the depths of 5, 10, 20, 30, and 40 mm for 90 days.

Based on the findings, the authors claimed that the sensor has excellent chloride sensing ability and well stable in an alkaline medium, and thus it is suitable to monitor  $\text{Cl}^-$  concentration in concrete structure. Gao et al. [46] produce all-solid-state  $\text{Cl}^-$  sensor employing  $\text{MnO}_2$  and Ag/AgCl electrodes. The potentiometric response and stability of the sensor was examined in synthetic concrete pore solutions with diverse NaCl concentrations ranging from 0.05–5.0 M. The performance of the sensor with the existence of interfering ions of  $\text{K}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Na}^+$ , and  $\text{SO}_4^{2-}$  was tested. The authors reported that the potentiometric response of the sensor to chloride is slightly influenced by the interfering ions, but considerably affected by the pH at low-chloride concentration.

**Table 3.** State-of-the-art  $\text{Cl}^-$  and pH potentiometric sensors details, test environment and their performance.

13	pH	Ir/IrO <sub>2</sub>	mortar	- wide range of depths	~160 days	The authors utilized an embeddable pH sensor based on thermally oxidized Ir/IrO <sub>2</sub> . The results from the sensor provide insight in the carbonation process and in the kinetic processes, such as transport and phases transformations.	2017	wired	[49]
14		IrO <sub>x</sub>	alkaline test solutions	- potential pH-response - reproducibility - accuracy - oxygen dependency	~2 years	The sensor is able to measure the pH with a maximum error of 0.5 units in a pH range of 9–13.5. It is stable, oxygen independent, and delivers precise and reproducible potential-pH responses. However, the electrode requires conditioning in highly alkaline solutions for at a minimum of 3–4 months. The formed (10–25 µm) thickness of the oxide layer is beneficial for long-term stability in concrete structure.	2017	wired	[50]
			mortar		160 days				
15		W/WO <sub>3</sub>	simulated concrete pore solution	- different pH values - interfering ions	10 months	The sensitivity was slightly decreased within the range from pH 5 to 12, but the responses are stable and repeatable to alkaline solutions (pH > 12). The sub-Nernstian response was observed within the range from pH 2 to 5. All the analysed interfering ions, SO <sub>4</sub> <sup>2-</sup> , K <sup>+</sup> , and Cl <sup>-</sup> , had no substantial impact on electrode potential. The electrode is robust, simple, low cost, and temperature resistant.	2010	wired	[51]
16 <sup>†††</sup>		thick-film Ag/Ag <sub>2</sub> O	simulated concrete pore solution	- to characterize the sensor	time varies based on the property under investigation	Ag <sub>2</sub> O electrodes exhibited excellent electrochemical response to pH variations in the solution. Indeed, electrode potential variation was observed when the Cl <sup>-</sup> concentration is about 10–2.5 M. With the rising of temperature, the average experimental slope slightly increases like the theoretical ones. In general, it reveals very good reproducibility, reversibility, and an acceptable response time. The sensor array allows the authors to monitor the carbonation progress in hardened concrete.	2016	wired	[52]
			concrete	- interfering ions - wide range of depths - response against temperature	19 days				
17 <sup>†</sup>		Ir/IrO <sub>x</sub> Ag/AgCl	solutions of different pH	- response against temperature - different pH values - Interrogator-sensor separation distance	2 days	By utilizing temperature compensation, a sensitivity of less than 0.1 pH was achieved with a response time of below 1 s. A resonant frequency change less than 8 kHz and a quality factor variation of 1.32 were obtained with separation distances between 2.5 and 8.5 cm. The temperature compensation ability and the design simplicity of the sensor make it suitable to be integrated by printed technology.	2013	wireless	[53]

<sup>†</sup> two integrated sensors, <sup>††</sup> more than two integrated sensors, <sup>†††</sup> manufactured using screen-printed technology.

Meanwhile, over the range of 5–45 °C, the sensor's potential reading linearly grows with the solution temperature. The sensor reveals outstanding polarization behaviour as proven by galvanostatic and potentiodynamic tests. Based on these facts, the author concluded that the sensor has excellent potential for  $\text{Cl}^-$  monitoring in concrete environments. Indeed, the authors recommend the pH of the concrete pore solution to be simultaneously monitored to accurately determine the  $\text{Cl}^-$  in slightly chloride contaminated concrete. Gao et al. [47], in another work, concluded the same after tested Ag/AgCl based potentiometric  $\text{Cl}^-$  sensor in synthetic concrete pore solutions with a wide range of NaCl concentrations ranging from 0.005–1.0 M.

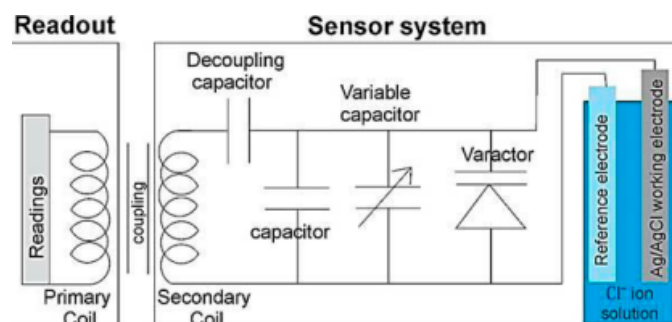

All the above short- and long-term evaluations of potentiometric Ag/AgCl based chloride sensors performed in pore solutions, mortar and concrete specimens demonstrated that Ag/AgCl electrode is stable and reliable in alkaline environments, and thus they could be suitable to monitor  $\text{Cl}^-$  concentrations in concrete structures. However, the main hurdles in realizing these sensors for monitoring concrete structures are the lack of appropriate sensors, which desirably have to be inexpensive, robust, and easily maintainable. Commercially available potentiometric chloride sensors typically utilize ISEs which show durability problems and can be costly. To address these problems, Gandía-Romero et al. [42] developed a potentiometric thick-film (screen-printed)  $\text{Cl}^-$  sensors made of Ag/AgCl resistive pastes, aiming to produce accurate, miniaturized, long-term, and inexpensive electrodes for monitoring  $\text{Cl}^-$  concentration in concrete. This technology is based on a printing method, which comprises a rubber palette to transfer inks via a display on the substrate surface. Screen-printed sensors are generally robust, inexpensive, and allow integration of multiple sensors in a small space. Sensors based on this technology are ideal for industrial mass production since it is possible to utilize resistive pastes, which are readily available in the market. The developed thick-film Ag/AgCl sensors are illustrated in Figure 1. These sensors were tested in concrete specimens. The reported test result demonstrated that the developed thick-film Ag/AgCl sensors could provide reliable and real-time measurements regarding the change of the  $\text{Cl}^-$  concentration in concrete specimens at different depths. The author concluded that the thick-film Ag/AgCl is a promising  $\text{Cl}^-$  sensor for concrete structure since it is robust, miniaturized, low cost, and have long-term stability.

**Figure 1.** Potentiometric thick-film  $\text{Cl}^-$  sensor arrays: (A) substrate dimensions and (B) real image [42].

The data transmission method of all the above mentioned potentiometric  $\text{Cl}^-$  sensors is through cables. There are few studies which demonstrate the possibilities of wireless monitoring of  $\text{Cl}^-$  in concrete element using potentiometric sensors. Abbas et al. [48] were able to wirelessly measure the  $\text{Cl}^-$  concentrations using sensor based on Ag/AgCl electrodes. The block diagram of the proposed wireless method for monitoring  $\text{Cl}^-$  using Ag/AgCl electrode is shown in Figure 2. The wireless communication was attained using a near-field-inductive coupling between the coils of the readout and the sensor. The potential of Ag/AgCl electrode is converted into capacitance by considering it as a bias potential for a varactor. The resonance frequency of the sensor coil alters because of the alteration in the capacitance of a varactor element attached to the Ag/AgCl electrode. This change is caused by the change in  $\text{Cl}^-$  concentration. Using near-field coupling, the resonance frequency is reflected on an

antenna. The communication does not need battery/external power. The authors were able to reliably measure the  $\text{Cl}^-$  concentrations (0.01 to 0.2 M) up to 35 mm between readout and sensor coil.

**Figure 2.** Block diagram of the wireless method for  $\text{Cl}^-$  monitoring using Ag/AgCl electrode [48].

Zhou et al. [39] proposed a wireless chloride sensor to monitor  $\text{Cl}^-$  concentration in concrete. The sensor is based on radio-frequency identification (RFID) communication protocol, which comprises an energy harvesting and management circuit, low-dropout (LDO) voltage regulator, microcontroller unit (MCU), RFID tag chip and three pairs of electrodes. These are: (i) calomel reference electrode, (ii) platinum, Pt, reference electrode, and (iii) Ag/AgCl electrode. The sensor tag powers its circuitry by harvesting energy which is radiated by the RFID reader. The authors also adopted a wavelet denoising approach to filter out the noise from the raw data which are corrupted by the noises in the wireless channel. In addition, monitoring software to display real-time measurements was developed. The performance of the sensor was tested in concrete with different  $\text{Cl}^-$  concentration. The authors claimed that the sensitivity of the developed wireless  $\text{Cl}^-$  sensor is high and the response time of the electrodes are sufficiently fast. The sensor reliably measures the  $\text{Cl}^-$  content in concrete within a communication distance of 16.3 m.

There are also studies which demonstrate the possibilities of integrating potentiometric sensors to monitor different parameters in a concrete environment. For instance, Duffó and Farina [40] developed integrated multifunctional sensors which monitor  $\text{Cl}^-$  content in concrete as well as open circuit potential and corrosion current density of rebar, electrical resistivity of concrete, oxygen availability, and inner temperature. The  $\text{Cl}^-$  sensor was developed based on Ag/AgCl electrodes. The evaluation of the sensors, in solutions of different pH values, exhibited acceptable stability and great reproducibility. The sensors have also demonstrated reasonably good stability when embedded in mortar for two years.

### 2.1.2. Potentiometric pH Sensors

Monitoring the pH of the concrete is vital since the alkalinity of the concrete has paramount importance in protecting the embedded rebar against corrosion. Though the use of potentiometric sensors for pH measurement is a common practice in various application areas, its use in monitoring the pH of the concrete pore solution is very limited. It can be noticed from Table 3 that Ir/IrO<sub>2</sub>, Ag/Ag<sub>2</sub>O, Ti/IrO<sub>2</sub>, W/WO<sub>3</sub>, and MO electrodes are used in recent time to monitor pH in a concrete environment. Femenias et al. [49] utilized embeddable potentiometric pH sensor based on thermally-oxidized iridium/iridium oxide (IrO<sub>x</sub>) electrodes. They continuously monitor pH at different depths over time in mortar specimens subjected to accelerated carbonation. The authors claimed that the utilized pH sensors can provide insight into the carbonation process and in the kinetic processes, for example, transport and phases transformations. These authors, in another work [50], examined the feasibility of IrO<sub>x</sub> electrodes for long-term continuous pH monitoring in a concrete environment, focusing on its reproducibility, stability, accuracy, and oxygen dependency. The sensor was exposed to highly alkaline solutions (pH 9–13.5) for about two years and they were able to measure with a maximum error of 0.5 pH units. They also examined its performance by embedding in mortar for about 160 days. The authors concluded that IrO<sub>x</sub> electrodes-based sensors are stable, accurate, oxygen independent,

and have outstanding ability for pH monitoring in a concrete environment. The formed (10–25  $\mu\text{m}$ ) thickness of the oxide layer is beneficial for long-term stability in concrete structure. Indeed, the authors indicated the essentiality of the  $\text{IrO}_x$  electrodes conditioning in highly alkaline solutions for a minimum of 3–4 months in order to achieve precise and reproducible potential responses. The response time of the electrodes are adequately fast for pH monitoring in a concrete environment. The schematic illustration and stereomicroscopy image of an  $\text{IrO}_x$  electrode that is developed to monitor pH in a concrete environment is shown in Figure 3.

**Figure 3.** Schematic illustration and stereomicroscopy image of pH sensor based on an  $\text{IrO}_x$  electrode [50].

Kolar et al. [51] examined the potentiometric response and stability of a  $\text{W}/\text{WO}_3$ -based chloride sensor by exposing it to saturated calcium hydroxide solution for 10 months. The sensitivity was slightly decreased within the pH range of 5–12, but the response was stable and repeatable in high-alkaline solutions ( $\text{pH} > 12$ ). The sub-Nernstian response was observed within the pH range of 2–5. None of the analysed interfering ions,  $\text{SO}_4^{2-}$ ,  $\text{K}^+$ , and  $\text{Cl}^-$ , had a substantial impact on electrode potential. The  $\text{W}/\text{WO}_3$  electrode is robust, simple, low cost, and temperature resistant. By considering all these facts, the author reported that  $\text{W}/\text{WO}_3$  electrode is applicable for the long-term monitoring of  $\text{Cl}^-$  in concrete environment.

Similar to chloride sensors, Gandía-Romero et al. [52] developed a screen-printed  $\text{Ag}/\text{Ag}_2\text{O}$  potentiometric pH sensor using thick-film technology and examined the performance of the sensor in simulated concrete pore solutions and concrete specimens. The performance evaluation of the sensor confirmed its reproducibility, reversibility, and acceptable response time. Based on these facts, the authors concluded that the screen-printed  $\text{Ag}/\text{Ag}_2\text{O}$  sensors can be embedded into concrete to continuously monitor pH in real time, which in turn provide insight regarding the carbonation front.

Bhadra et al. [53] reported the development of an integrated wireless passive sensor which can monitor pH and temperature simultaneously in a concrete environment. This sensor comprises a pH electrode ( $\text{Ir}/\text{IrO}_x$ ), and a reference electrode ( $\text{Ag}/\text{AgCl}$ ), a thermistor, a voltage sensing circuit and an interrogator coil which is inductively connected to the inductor of the sensor. The sensor was calibrated with a range of 25–55  $^{\circ}\text{C}$  and 1.5–12 for temperature and pH, respectively. By utilizing temperature compensation, a sensitivity of less than 0.1 pH was achieved with a response time of below 1 s. Nonetheless, this sensor is unstable to interference by the existence of other ionic matters. The authors claimed that the temperature compensation capacity and the design simplicity of the sensor make it suitable to be integrated by printed technology, so that the sensor will be used to remotely monitor pH in a concrete environment [53].

### 2.1.3. Potentiometric Integrated Chloride Ion and pH Sensors

Monitoring of  $\text{Cl}^-$  concentrations and pH at rebar/concrete interface is imperative for detecting rebar corrosion at early stage and to make sound decisions. In this regard, there are some attempts which show the possibility of integrating chloride and pH sensors to monitor both parameters ( $\text{Cl}^-$  concentrations and pH values) simultaneously. For example, Du et al. [54] developed and presented an integrated sensor unit that monitor pH values and  $\text{Cl}^-$  concentration at the interface of rebar and concrete. The pH and the chloride sensors are based on Ir/IrO<sub>2</sub> and Ag/AgCl electrodes, respectively. The sensor was embedded in the concrete to simultaneously monitor pH of the pore solution and the amount of  $\text{Cl}^-$  concentrations. The reported test results revealed that the integrated sensor is stable and robust, indicating the potential of the sensor to realize continuous in-service monitoring of pH and  $\text{Cl}^-$  concentrations in concrete.

There are also pH and  $\text{Cl}^-$  sensors, which are integrated with other sensors that monitor different parameters in concrete environment. For example, Yu and Caseres [55] developed an embeddable prototype of an integrated multifunctional sensor unit. It encompasses electrodes of Ag/AgCl, metallic oxide (MO), a multi-electrode array sensor (MAS), and a four-pin (Wenner) array stainless steel for monitoring of  $\text{Cl}^-$  concentrations, pH, microcell corrosion current, and localized concrete resistivity, respectively. The long-term sensitivity and reliability of the prototype sensor was evaluated by embedding it in a cement paste cylinder. The claimed results (based on a year of monitoring) indicated that the pH and the other integrated sensors were reliable and stable, showing its potential to be implemented in real RC structures. Figure 4 illustrates the proposed multifunctional sensor unit. Dong et al. [56] also developed multifunctional sensor to monitor pH of the pore solution,  $\text{Cl}^-$  concentration in concrete, corrosion current, and equilibrium potential of rebar. The pH sensor was developed from Ti/IrO<sub>2</sub> electrode, while the  $\text{Cl}^-$  sensor from Ag/AgCl electrode. The reported results of the investigation demonstrated that all the sensors (including pH and  $\text{Cl}^-$ ) were stable and reliable while providing great potential responses. Hence, this multifunctional sensor is suitable for long-term in-service monitoring of corrosion causing parameters.

**Figure 4.** Image of the sensor package configuration, adopted from [55].

### 2.2. Fiber-Optic Sensors

As ISEs measurement, optical techniques are one of the oldest and well-established methods for detecting chemical analytes and have shaped the foundation for several chemical sensors. The optical based sensing technology is not based on a single concept but on a variety of optical phenomena that can be applied to measure a wide range of chemical and physical parameters [57,58]. The evolution of low-cost high-quality optical fibers has facilitated the wide development and adoption of optical fiber sensors. A fiber-optic sensor (FOS), in its simplest form, comprises optical fiber, light source, sensing element, and detector. The fundamental operation principle of fiber-optic sensors is that the sensing element modulates one or more parameters of the optical system (e.g., wavelength, chromatic,

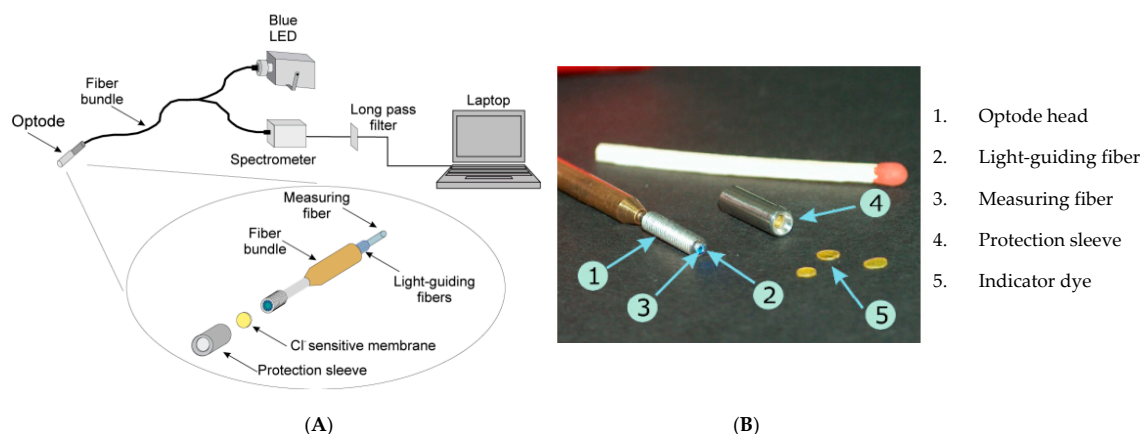

phase, polarization, etc.), which results in a change in the optical signal characteristic at the detector. FOS can influence the light-guiding features of the transmitting fiber and correlate the specific attributes to the changes of the light. The basic principle is to evaluate an external physical parameter by causing changes in the optical characteristics of a light beam passing inside and along an optical fiber. The fiber is therefore both the transmission medium and the sensing element [58].

In the past four decades, there has been substantial research attempt in developing optical fiber-based sensors for both chemical and physical analytes. Accordingly, several interesting schemes have been made and continue to be the subject of significant research. Application areas for chemical analysis involve laboratory-based analysis, environmental monitoring, and clinical diagnosis applications. Every area of specific application has their own prerequisites for selectivity, sensitivity, accuracy, robustness, and cost. The studied physical state of the analytes comprised gases, dissolved gases, liquids, ions in solution, and solids [57]. With FOS, chemical analysis can often be carried out in situ and in real time using various approaches, which are: fluorescence, scattering, colour change, absorption, evanescent wave interaction, and refractive-index change [58]. Fiber-optic fluorescence techniques have been used to measure various types of ions, such as chloride, iodide, iron, plutonium, and sulphate. It has also been expanded to measure pH.

### 2.2.1. Fiber-Optic Chloride Ion Sensors

Recently, few numbers of fiber optic-based sensors to monitor  $\text{Cl}^-$  concentrations in concrete environment was developed. Ding et al. [59] have developed  $\text{Cl}^-$  sensor using a suspended-core optical fiber for in-situ real-time monitoring. The predominant property of suspended-core optical fiber is its big air holes running throughout its length, and thus sensitive material could be stored into the holes. This type of optical fiber has extended interaction length, powerful light-matter interaction and utilization of small sample amounts [59]. They introduced a sol-gel membrane to immobilize lucigenin (used as a fluorescence sensitive material) over the internal wall of the suspended-core optical fiber using dip-coating technique. The performance of the sensor with interfering ions ( $\text{Na}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{SO}_4^{2-}$ , and  $\text{OH}^-$ ) that can be occurred in concrete was tested. The authors claimed that the sensor works in high-alkaline environments.  $\text{Na}^+$ ,  $\text{Ca}^{2+}$ , and  $\text{Mg}^{2+}$  have minor influence on  $\text{Cl}^-$  detection of the fiber-optics sensor and high amount of  $\text{SO}_4^{2-}$  slightly hamper the process of lucigenin quenching. The  $\text{OH}^-$  has a major interference in  $\text{Cl}^-$  detection of the sensor. Based on the results, the authors claimed that the developed sensor could be successfully applied for  $\text{Cl}^-$  monitoring in concrete structure. Laferrière et al. [60] has developed optical fiber for real-time and continuous monitoring of  $\text{Cl}^-$  concentrations in concrete pores. It uses  $\text{Cl}^-$  sensitive fluorescence indicator dye. The performance of the developed sensor was tested in mortar specimens at various depths in two simulated climatic conditions: (i) hot maritime and (ii) cold environment. The authors reported that it is possible to precisely quantify the  $\text{Cl}^-$  concentrations in both climatic conditions, indicating its applicability for scientific studies and condition monitoring of concrete structure. The schematic representation of the optical fiber based  $\text{Cl}^-$  sensor measurement setup and the components of the sensor is illustrated in Figure 5.

**Figure 5.** (A) Schematic representation of optical fiber based  $\text{Cl}^-$  sensor measurement setup, (B) components of the sensor [60].

### 2.2.2. Fiber-Optic pH Sensors

Though fiber-optic fluorescence techniques are applied to measure pH in various fields of study, its application in concrete environments is yet limited. Nguyen et al. [3,61] produced an optical fiber sensor using pH sensitive fluorescent polymer to monitor pH of concrete pores. The authors stated that the sensor provides responses over the appropriate pH range for concrete with an acceptable rate of around 50 min and is stable over a period of 20 months. They also reported that the sensor has trivial cross sensitivity to ionic strength and outstanding photostability in a series of tests. All these characteristics make the sensor suitable for long-term in-service monitoring of pH in concrete. McPollin et al. [62] prepared tailor-made fiber-optic sol-gel-based pH sensors aiming to have a more suitable characteristic in concrete environments. It was produced by applying the sol-gel coating (manufactured from tetraethyl orthosilicate (TEOS)) onto a plastic clad silica fiber with a core diameter of 600  $\mu\text{m}$ . The adopted indicator dye was cresol red, which has pH range from 8–13. Hydrochloric acid (HCl) was applied as a catalyst solution. The performance of the sensor was assessed by embedding it in cement mortar cubes for more than 18 months and it was functional through the testing period.

### 2.3. Comparison between Potentiometric and Fiber-Optic Sensors

As discussed earlier, the operational technique of the potentiometric and fiber-optic sensors is different. Since both types of sensing devices are based on their own specific principles; they are affected by different parameters. Thus, the comparison between them is focused on their production process, invasiveness, and performance.

The production process of potentiometric sensors is simple which adopts the well-known electrochemical processes, whereas the fiber-optic sensors are highly technical and complicated. Regarding invasiveness, both types of sensing devices have negligible effect on the structural behaviour of the infrastructure because they are small compared with the size of the structural element under investigation. They also have no impact on the surrounding environment during measuring  $\text{Cl}^-$  and pH in the concrete element.

The overall performance of the potentiometric sensors largely depends on the types and preparation of the electrodes. As several of the parameters (such as the types of electrodes, the production processes of the sensors, the test environment, and test duration of the sensors) presented in Table 3 are varying considerably, it is impossible to compare the performance of the sensors, rather providing the general observations. Generally, all the potentiometric sensors presented in Section 2 are sufficiently accurate and stable based on the measurements taken up to the period of two years. Both the potentiometric as well as the fiber-optic sensors can be affected by the presence of some interfering ions. However, more types of ions can interfere with the potentiometric based sensing devices than FOS. The fiber-optic sensors are found to be more chemically stable than potentiometric sensors.

### 3. Internet of Things Based Corrosion Monitoring

The  $\text{Cl}^-$  and pH sensors presented above can be embedded in real RC structures for corrosion monitoring as almost all the authors concluded that both potentiometric and fiber-optic sensors are reasonably precise, stable, and reliable. This allows avoiding the conventional laboratory based destructive testing and paves a way for continuous monitoring. All but three of the sensors that are presented in Section 2 transfer their measurement to a data logger through wired connection. Deployment of such kind of wired sensors in spatially dispersed concrete elements of a particular structure bears substantial costs for installing and retaining the wired system. It is also inflexible and unattractive aesthetically. Three of the sensors [39,48,53] that employ wireless communication for transmitting their measurements use very short-range communication technology that require close-range reading. This limits their applicability for continuous long-term monitoring. The above reviewed sensors were tested for up to two years, which is very short compared to the service life of RC structures that often spans about 50–80 years. This requires reliable operation of sensors for a long period. This could be achieved through the integration of self-diagnosis and self-repair capability in the sensing subsystems and/or possibility to easily replace them without affecting the monitoring system. It is also necessary to have energy scavenging capability for ensuring the availability of energy sources despite depleted battery sources. In the area of structures, the commonly employed energy scavenging method is converting vibrations into electrical energy. A review of energy harvesters that converts vibrations into electrical energy can be found in [63].

The IoT is a networked system where distributed sensors monitor physical events and transmit the measurements through wireless communication medium to a remote user. IoTs have been proposed for a number of different applications, such as healthcare [64–66], environmental monitoring [67–69], smart home and city [70–72], and structural health monitoring [73–75]. The main components of IoT are sensor nodes (comprising sensors, low-power computing devices, and radio modules for wireless communication), gateway/edge devices, and cloud as illustrated in Figure 6. Several low-power and low-complexity computing devices are developed for IoT applications, which are usually battery powered. The sensors are integrated to the computing device through wired connection. The computing device performs signal processing operations on the sensor's measurement according to the application requirements and prepares it for transmission by the integrated/interconnected radio module.

**Figure 6.** Schematic representation of the main components of IoT.

Various low-power communication technologies are developed for transmitting the data from the computing device to the gateway. These technologies differ in their communication range, spectrum usage, bandwidth requirement and power consumption. For corrosion monitoring of RC

structures, communication technologies that have 100 m or longer communication range, such as Zigbee [76], LoRa [77], Sigfox [77], and narrowband IoT [77], are better choices. The long-range communication technologies, such as LoRa, Sigfox, and narrowband IoT enable wide area networks mainly using a star topology where the measurement is directly communicated to the gateway without the need for a relay node. These technologies are a better option for monitoring large RC structures in a cost-effective manner as it requires a smaller number of nodes. LoRa and Sigfox operate in the unlicensed spectrum where Sigfox requires some form of subscription fee. Narrowband IoT uses licensed spectrum, which needs payment for the service to a mobile service provider. The gateway is connected on one side to the IoT's low-power computing nodes through low-power wireless communication technologies and on the other side to the edge device/cloud through the Internet. The gateway translates the communication protocol and forwards the data to the edge device/cloud. The collected data in the edge device/cloud is processed and communicated with the remote user through appropriate web applications.

IoT-based corrosion monitoring system has advantages over wired sensors with datalogger systems in terms of continuous measurements, cost effectiveness, flexibility, remote monitoring, ease of deployment and maintenance. There have been proposals on the use of wireless sensor networks for corrosion detection [78–81] and IoT for structural health monitoring [73–75]. Among these works, Qiao et al. [79], Sun et al. [80], and Xu et al. [81] employed IEEE802.15.4-based short-range connectivity for corrosion monitoring while Abdelgawad and Yelamarthi [74] used WiFi connectivity for structural health monitoring. The rest of the works have failed to mention the specific connectivity technology that is considered in their work. The choice on short- vs. long-range connectivity technology depends on the size of the structure and aesthetic importance besides specific performance requirements of the communication technology. IoT nodes can be deployed on any type of RC structures and deliver facility managers/owners with indispensable real-time data on the corrosion condition of the structure, and thus making informed decisions.

#### 4. Evolution of Data-Driven Corrosion Assessment

With the emerging IoT based low-cost continuous monitoring system, speculating about where the future might lead in corrosion assessment of RC structures is interesting. It is well known that smart environments based on IoTs and complex data analytical techniques represent the next evolutionary development step in various disciplines, including transport [82], military [83], agriculture [84,85], and civil engineering [30]. The complex data analytics is often performed using machine learning and/or deep learning methods. Machine learning is a subdomain of artificial intelligence that engages design and implementation of algorithms to recognize intricate patterns out of data and make intelligent decisions [86–94]. It models profound relationships in data inputs and reconstructs a knowledge scheme. Machine learning based models can be predictive to carryout prediction or descriptive to discover knowledge from data, or both without assuming a predetermined equation as a model [90,95,96]. It is one of the foremost outstanding technological developments in recent history and used in various disciplines, e.g., computational finance [97–99], image and speech processing [100–102], property valuation [103–105], computational biology [106–108], and energy production [109–111]. Deep learning is a subset of machine learning that uses multiple layers to progressively extract features from the raw input data [112]. Both, machine learning and deep learning, have strong abilities to handle heterogeneous and large volume of data and achieve high accuracy and reliability, which make them suitable for making a correct decision for various complex problems. Even if employing intelligent data analytics is already becoming a common practice in different disciplines, since recent times, its use in the field of concrete durability is at its infancy. For example to detect rebar corrosion [79,81,113], to characterize carbonation resistance [114–120],  $\text{Cl}^-$  permeability [121–126], hygrothermal performance in concrete [127,128],  $\text{Cl}^-$  diffusion coefficient [129–132], chloride penetration and carbonation predictors [116,133], and. Indeed, these works largely employ short-term data generated either from accelerated laboratory tests

or field tests, but not real-time data from embedded sensors. A comprehensive review regarding the application of machine learning in the field of concrete durability is found in [134].

Continuous in-situ monitoring of parameters that initiate and accelerate rebar corrosion in concrete structure is crucial to avoid corrosion associated damage. An early detection of corrosion risks assists engineers to plan optimal maintenance measures in a timely and cost-effective manner. Long-term in-situ monitoring of such parameters has also the utmost importance in better understanding of the complex corrosion phenomenon. With the current development of sensing technology, realization of miniaturized sensors, that are stable, accurate, robust, and low-cost, for monitoring durability performance of RC structures will grow in years to come. These sensors can be employed in RC structures to monitor factors that control corrosion of rebar or other deterioration mechanisms, even in remote locations that are normally inconvenient to access. Data acquired from several sensors will be fused using machine learning and/or deep learning methods. The fused data will then be used to evaluate the status of the structures autonomously by applying appropriate algorithm(s). Several machine learning algorithms such as k-nearest neighbors, linear models, decision trees, ensembles of decision trees, and support vector machine as well as deep learning algorithms such as convolutional neural network, recurrent neural networks, long short-term memory networks and deep belief networks, have the potential to be employed for realizing autonomous corrosion assessment method. Thus, the application of IoT systems and intelligent data analytics will form a principal element in lifecycle management of RC structures.

Autonomous corrosion assessment utilizing IoT systems and advanced data analytics is illustrated in Figure 7. As can be seen in the figure, chloride and pH sensors are embedded in RC structures along with other relevant sensors such as moisture and temperature sensors. As it is described earlier, moisture and temperature affect the critical chloride threshold. These environmental loads are also the major factor that are controlling the corrosion rate of rebar. The moisture amount within the concrete governs the corrosion rate through their influence on the electrochemical reactions at the rebar-concrete interface and ions transport between anodes and cathodes [12]. The surrounding temperature controls the rate of rebar corrosion since it influences the electrochemical reactions and the moisture amount that the concrete retains [135]. For example, the rate of corrosion differs by more than a factor of ten in a regular seasonal temperature range of 5 to 30 °C [6,135,136]. Thus, continuous hygrothermal monitoring of concrete is necessary. This provides more reliable information about the actual hygrothermal behavior of the concrete. Today, there are several studies which show the applicability of wireless sensors for monitoring moisture and temperature in concrete environments [81,137–139]. Continuous monitoring of such parameters using sensing devices will deliver more reliable data compared to carrying out periodic field testing. In the long term, this approach leads to cost savings, considering the users cost, the labour cost, and their safety into account. This is because such a monitoring system delivers continuous in-service data without the involvement of inspection crews on the field. By applying machine learning and or deep learning on the collected data, accurate corrosion assessment can be computed in the cloud autonomously and communicated to remote stakeholders. This allows the responsible parties to carry out condition-based maintenance actions in a timely manner, and thus alleviates maintenance-associated costs substantially. Such autonomous corrosion condition assessment methods, which add a digital layer to the physical infrastructure, make the infrastructure smart. Scientists and other interested parties can make use of the data available in the cloud to carry out in-depth studies, which enable them to generate new knowledge that help to address corrosion associated damages. The uncovered scientific knowledge will support material engineers to design robust concrete solutions that enhance the durability of the infrastructure. In addition, the long-term data and its analysis assist engineers to devise optimal maintenance plans.

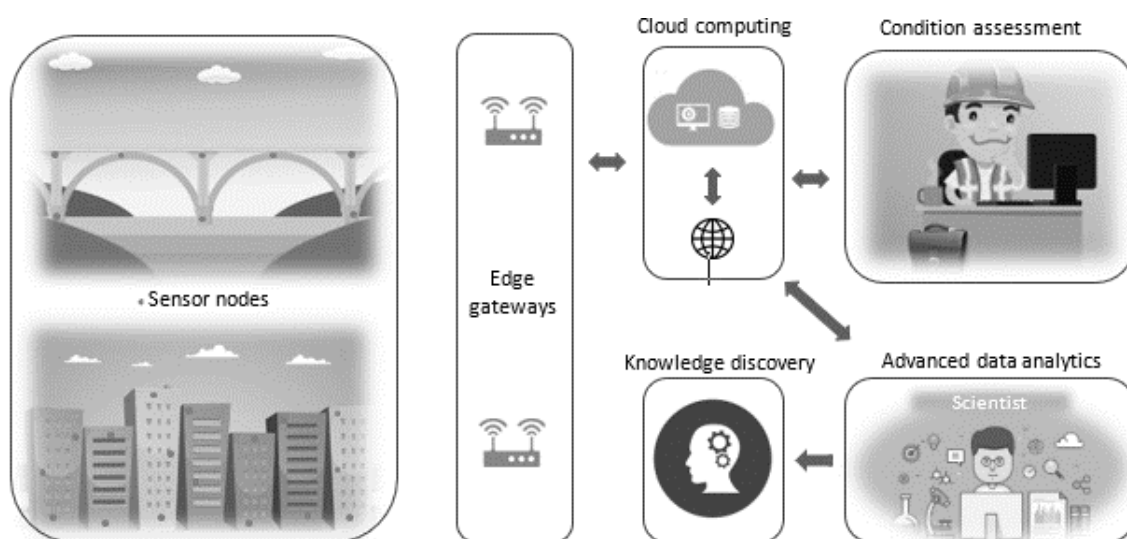

Figure 7. Schematic presentation of autonomous corrosion assessment.

## 5. Conclusions

Continuous monitoring of corrosion-causing factors in a reliable and cost-effective manner is vital to plan accurate condition-based maintenance strategies for RC structures. In this paper, state-of-the-art pH and  $\text{Cl}^-$  sensors that are proposed for monitoring the carbonation front and  $\text{Cl}^-$  concentration in concrete environment are critically reviewed. Based on their measuring principles, the sensors utilized in concrete environment for monitoring pH and  $\text{Cl}^-$  concentration can be categorized into two: potentiometric and fiber optic. The majority of the studied pH and  $\text{Cl}^-$  sensors have showed high sensitivity, reliability, and stability in concrete environment, though the experiments were carried out for relatively short periods. The review work also identified three cases that attempted to monitor the  $\text{Cl}^-$  in concrete wirelessly albeit very short range. In addition, this work speculates where the future might lead in corrosion condition assessment of RC structures. With the technology development of sensors along with IoT-based systems, and machine learning, autonomous corrosion condition assessment remotely in a cost-efficient manner will become feasible. The collected sensor data can be analysed further by engineers and scientists for greater understanding concerning the intricate corrosion phenomena. The new scientific knowledge will help scientists to design optimum solutions that increase the durability of infrastructure and to build proactive maintenance plans.
