Abstract

A highly active anode material for solid oxide fuel cells resistant to carbon deposition is developed. Co-Fe co-doped \(\text{La}_{0.5}\text{Ba}_{0.5}\text{MnO}_{3-\delta}\) with a cubic-hexagonal heterogeneous structure is synthesized through the pechini method. An A-site ordered double perovskite with \(\text{Co}_{0.94}\text{Fe}_{0.06}\) alloy-oxide core-shell nanoparticles on its surface is formed after reduction. The phase transition and the exsolution of the nanoparticles are investigated with X-ray diffraction, thermogravimetric analysis and high-resolution transmission electron microscope. The exsolved nanoparticles with the layered double perovskite supporter show a high catalytic activity. A single cell with that anode and a 300 \(\mu\text{m}\)-thick \(\text{La}_{0.8}\text{Sr}_{0.2}\text{Ga}_{0.8}\text{Mg}_{0.2}\text{O}_{3-\delta}\) electrolyte layer exhibits maximum power densities of 1479 and 503 mW cm\(^{-2}\) at 850 °C with wet hydrogen and wet methane fuels, respectively. Moreover, the single cell fed with wet methane exhibits a stable power output at 850 °C for 200 h, demonstrating a high resistance to carbon deposition of the anode due to the strong anchor of the exsolved nanoparticles on the perovskite parent. The oxide shell also preserves the metal particles from coking.

\textbf{Keywords:} Anode; Solid oxide fuel cell; \textit{in situ} exsolution; Hydrocarbon; Layered perovskite; Core-shell structure
1. Introduction

Solid oxide fuel cells (SOFCs) are one of the most promising technologies converting chemical energy in fuels into electric power with high efficiency and low emissions. Due to its relatively high operating temperatures (600-1000 °C), SOFCs offer excellent fuel flexibility, which makes the utilization of the abundance and low cost hydrocarbon fuels possible.\(^1\) Methane is a potential fuel for SOFCs due to its abundant reserves and high H/C ratio compared with other hydrocarbons, which results in low CO\(_2\) emissions. However, the strong carbon-hydrogen bonds in CH\(_4\) sluggish its electrochemical oxidation kinetics,\(^4\) and thus the development of anode materials with a sufficient catalytic activity is highly demanded.\(^5\)\(^-\)\(^7\) Ni-based cermet anodes face aggregation at high temperature and serious carbon deposition with hydrocarbons as fuels.\(^8\)\(^-\)\(^9\) As promising substitutes, ABO\(_3\) perovskite oxides show a high coking resistance and sulphur tolerance.\(^10\) Nevertheless, most of the perovskite anodes which are stable in a reducing atmosphere, such as chromites, titanates and vanadates, possess either low electrical conductivity or low electrocatalytic activity.\(^11\)\(^-\)\(^14\) In 2006, Huang et al.\(^15\) developed a series of double-pervoskite anode materials such as Sr\(_2\)MgMoO\(_{6-\delta}\) and Sr\(_2\)MnMoO\(_{6-\delta}\). A single cell with Sr\(_2\)MgMoO\(_{6-\delta}\) anode and a 300 \(\mu\)m-thick La\(_{0.8}\)Sr\(_{0.2}\)Ga\(_{0.83}\)Mg\(_{0.17}\)O\(_{2.815}\) electrolyte layer exhibited a maximum power density \(P_{\text{max}}\) of 438 mW cm\(^{-2}\) and a quasi-steady performance for 50 power cycles at 800 °C with dry CH\(_4\) as the fuel.

The coupling of active metallic catalysts and mixed ionic-electronic conducting supporters is a promising strategy to develop new anode materials with both high catalytic activity and conductivity. However, the conventional infiltration process is time-consuming, and the metallic particles trend to agglomerate at high temperature.\(^16\) Alternatively, catalytic metal atoms can be incorporated into B sites of the host perovskite lattice during the synthesis process in an oxidizing atmosphere and then exsolve as uniform-sized nanoparticles evenly distributed during the following reduction process,
which show high and stable catalytic activity for automotive emissions control.\textsuperscript{17, 18} The exsolution in anodes of SOFCs in earlier works were mainly driven by the inherent reducibility of B-site dopant cations, and the exsolved catalysts were limited to precious metals such as Ru,\textsuperscript{19, 20} Pt\textsuperscript{21} and Pd,\textsuperscript{22} and Ni which showed low stability due to agglomeration.\textsuperscript{23} In recent years, much effort has been focused on the strategies to facilitate the exsolution, such as A-site deficiency,\textsuperscript{24} crystal structure transformation,\textsuperscript{25} and electrochemical switching,\textsuperscript{26} and the exsolution of cheap and stable transition metals, such as Co, Fe and their alloys, have been widely investigated. A K\textsubscript{2}NiF\textsubscript{4}-type structured Pr\textsubscript{0.8}Sr\textsubscript{1.2}(Co,Fe)\textsubscript{0.8}Nb\textsubscript{0.2}O\textsubscript{4+δ} material with Co-Fe alloy exsolved on its surface was obtained by annealing perovskite Pr\textsubscript{0.4}Sr\textsubscript{0.6}Co\textsubscript{0.2}Fe\textsubscript{0.7}Nb\textsubscript{0.1}O\textsubscript{3-δ} in H\textsubscript{2} at 900 °C, and a single cell with that anode achieved $P_{\text{max}}$ of 0.6 W cm\textsuperscript{-2} and 0.92 W cm\textsuperscript{-2} at 850 °C using wet CH\textsubscript{4} and C\textsubscript{3}H\textsubscript{8} as fuels, respectively.\textsuperscript{27, 28} Very recently, Chen et al.\textsuperscript{29} found that the size and iron content of Co\textsubscript{1-x}Fe\textsubscript{x} nanoparticles exsolved from La\textsubscript{0.5}Sr\textsubscript{0.5}Co\textsubscript{0.45}Fe\textsubscript{0.45}Nb\textsubscript{0.1}O\textsubscript{3-δ} increase with the increase of temperature and reduction time in wet H\textsubscript{2}. Lai and Manthiram\textsuperscript{30, 31} studied the exsolution and reincorporation of Co-Fe nanoparticles on the surface of La\textsubscript{0.3}Sr\textsubscript{0.7}Cr\textsubscript{0.3}Fe\textsubscript{0.6}Co\textsubscript{0.1}O\textsubscript{3-δ} during redox cycles at 700-800 °C. The material shows a high redox reversibility at 700 °C, bringing about a stable anode performance with H\textsubscript{2} and C\textsubscript{3}H\textsubscript{8} as fuels.

A-site ordered double-perovskites LnBaMn\textsubscript{2}O\textsubscript{5+δ} (Ln means lanthanides such as Pr, Nd and Sm) and their derivatives have been widely investigated as ferromagnetic materials.\textsuperscript{32, 33} In the last few years, they have attracted attention as fuel electrodes of SOFCs and solid oxide electrolyzer cells due to their high oxygen ionic diffusion rate and high electronic conductivity.\textsuperscript{34-43} A layered structure [LnO\textsubscript{δ}]-[MnO\textsubscript{2}]-[BaO]-[MnO\textsubscript{2}]-[LnO\textsubscript{δ}] along the c axis is formed accompanied with the loss of lattice oxygens during the reduction. The oxygen vacancies formed in the [LnO\textsubscript{δ}] planes facilitate the electrochemical oxidation of fuels and provide two-dimensional channels for the fast conduction of
oxygen ions. A 300 μm-thick \( \La_{0.9}\Sr_{0.1}\Ga_{0.8}\Mg_{0.2}\O_{3-\delta} \) electrolyte-supported single cell with \( \Pr\Ba\Mn_{2}\O_{5+\delta} \) (PBM) as the anode obtained a \( P_{\text{max}} \) of 0.57 W cm\(^{-2}\) at 850 °C using H\(_2\) as fuel. In order to improve the catalytic activity of PBM further, late transition metals have been doped in the B sites, and their exsolution is facilitated during the structure transformation. Nanoparticles of metallic Co were exsolved \textit{in situ} from Co-doped PBM and exhibited high catalytic activities towards syngas/ethane oxidation and soot combustion. Fe, Co and Ni were incorporated into the PBM anode, which improved the performance of the SOFCs fed with H\(_2\) and C\(_3\)H\(_8\). Nevertheless, the catalytic activities of doped PBM anodes for the electrochemical oxidation of CH\(_4\) are still limited.

LaMnO\(_3\) and its derivatives have been widely used as catalysts for complete oxidation of methane. Liu et al. investigated \( \La_{1-x}\A_{x}\MnO_3 \) (\( \A=\Ba, \Sr, \Ca \)) as catalysts for methane oxidation, among which \( \La_{0.8}\Ba_{0.2}\MnO_3 \) showed the highest activity. The conversion of CH\(_4\) oxidation over \( \La_{0.5}\Ba_{0.5}\MnO_3 \) nanocubes achieved 100% at 600 °C, and maintained at 97% after running at 560 °C for 50 h. Meanwhile, it has been proved that the diffusivity of oxygen in A-site cation ordered perovskite increases with the increase of the radius of the lanthanide element. La\(^{3+}\) is a potential candidate for the A-site cation in double-perovskite oxidation catalysts due to its largest size in the lanthanide ions. However, \( \La_{1-x}\Ba_{x}\MnO_{3-\delta} \) derived double perovskites have been rarely studied as anodes of SOFCs by now.

In this work, \( \La_{0.5}\Ba_{0.5}\Mn_{1-x}(\Co\Fe)_x\O_{3-\delta} \) (\( x = 0-0.2 \)) is studied for the first time as an anode material for SOFCs with hydrogen and methane as fuels. The phase transition and the exsolution of B-site elements during the reduction process are investigated, and the formation of the double-perovskite structure is proved. Metal-oxide nanoparticles with a core-shell structure exsolve from the
double-perovskite parent, which improve the catalytic activity of the anode significantly. The anode also shows a high stability in methane atmosphere.

2. Experimental

2.1. Preparation of Materials

La$_{0.5}$Ba$_{0.5}$MnO$_{3-\delta}$ (LBM), La$_{0.5}$Ba$_{0.5}$Mn$_{0.9}$Fe$_{0.05}$Co$_{0.05}$O$_{3-\delta}$ (LBMFC-1) and La$_{0.5}$Ba$_{0.5}$Mn$_{0.8}$Fe$_{0.1}$Co$_{0.1}$O$_{3-\delta}$ (LBMFC-2) powders were synthesized through the pechini method.$^{34,38}$ Stoichiometric La(NO$_3$)$_3$·6H$_2$O (99.9%, Aladdin), Ba(NO$_3$)$_2$ (99.5%, Aladdin), Mn(NO$_3$)$_2$ solution (AR, 50 wt.% in H$_2$O, Aladdin), Co(NO$_3$)$_2$·6H$_2$O (99.99%, Aladdin) and Fe(NO$_3$)$_3$·9H$_2$O (99.99%, Aladdin) were dissolved in distilled water. Citric acid (99.5%, Aladdin) and ethylene glycol (Guangfu fine chemical, Ltd., China) were added into the solution as complexation agents. The concentrations of metal cations, citric acid and ethylene glycol were 0.2, 0.6 and 0.3 mol L$^{-1}$, respectively. The pH of the solution was kept at about 8 with the addition of ammonium hydroxide. The aqueous solution was kept at 85 °C under a continuous stir. The gel formed was slowly decomposed at 350 °C to form a black precursor, and further grounded and calcined at 950 °C for 4 h to form anode powders. For characterization, the powders were treated with 5% H$_2$-95% Ar at 850 °C for 5 h, which were denoted as D-LBM, D-LBMFC-1 and D-LBMFC-2, respectively. The synthesis procedures of La$_{0.4}$Ce$_{0.6}$O$_{2-\delta}$ (LDC) buffer layer and Ba$_{0.5}$Sr$_{0.5}$Co$_{0.8}$Fe$_{0.2}$O$_{3-\delta}$ (BSCF) cathode powders have been introduced in previous publications.$^{15,52}$

2.2. Characterization

The crystal structures of the anode powders before and after reduction were investigated at room temperature via X-ray diffraction (XRD) with a D8 Focus diffractometer (Bruker Corp., Cu-K$\alpha$ radiation, 40 kV and 200 mA). Thermogravimetric analysis (TGA) of fresh samples was carried out in 5% H$_2$-95% Ar at a heating rate of 10 °C min$^{-1}$ in a NETZSCH thermal analyzer (STA, 449F3).
High-resolution transmission electron microscopy (HRTEM), high-angle annular darkfield scanning TEM (HAADF-STEM) and energy dispersive X-ray (EDX) analyses were performed using a transmission electron microscope (JEOL JEM 2100) equipped with a Schottky cold emission gun and an EDX analyzer. Hydrogen temperature programmed reduction (H\textsubscript{2}-TPR) was performed in an Autochem II 2920 instrument (Micromerritics, USA) equipped with a thermal conductivity detector. The samples were pretreated with helium at 300 °C for 2 h and subsequently cooled down to 50 °C. Then H\textsubscript{2}-TPR was performed in 10% H\textsubscript{2}-90% Ar with a flow rate of 50 mL min\textsuperscript{-1} from 50 to 800 °C at a rate of 10 °C min\textsuperscript{-1}. X-ray photoelectron spectroscopy (XPS) analysis was performed using a Thermo ESCALAB 250Xi XPS imaging spectrometer. The XPS spectra were referenced to the C 1s bonding energy (284.8 eV). The surface and cross-sectional morphologies of the single cells were characterized with a scanning electron microscope (SEM, S-4800, Hitachi, Japan).

The electrical conductivities of the samples were measured via a four-probe direct current method. The powders of LBM, LBMFC-1 and LBMFC-2 were pressed into rectangular bars and then sintered at 950 °C in air for 12 h. The bars were reduced in 5% H\textsubscript{2}-95% Ar at 850 °C for 5 h. Then the electrical conductivity was measured with an electrochemical workstation (VersaSTAT 3, Ametek) in 5% H\textsubscript{2}-95% Ar and air, respectively.

2.3. Cell Fabrication and Test

La\textsubscript{0.8}Sr\textsubscript{0.2}Ga\textsubscript{0.8}Mg\textsubscript{0.2}O\textsubscript{3-δ} (LSGM) electrolyte powder (Fuel cell materials Co., USA) was pressed into pellets with a diameter of 20 mm under 200 MPa, and subsequently sintered in air at 1450 °C for 20 h. The obtained pellet was polished to achieve a thickness of 300 μm. LBM, LBMFC-1, LBMFC-2, BSCF and LDC powders were mixed with a binder (V006, Heraeus Ltd.), respectively, to form slurries. The LDC slurry was screen-printed on the LSGM layer and sintered at 1400 °C for 2 h to form a buffer layer\textsuperscript{15}. The anode slurry was printed on the LDC layer, and the BSCF slurry was printed
on the other side of the electrolyte layer. The geometrical areas of the anode and cathode were both 0.5 cm$^2$. The pellet was finally calcined at 950 °C in air for 4 h. Both electrodes were coated with Ag paste as current collectors.

Before the performance test, the anode of the cell was reduced at 850 °C in 5% H$_2$-95% Ar for 2 h. The cells were tested with humidified H$_2$ and CH$_4$ (with 3% H$_2$O) as fuels and oxygen as oxidant. All the gases were supplied at a flow rate of 100 ml min$^{-1}$. The electrochemical impedance spectra (EIS) of the cells were recorded from 1 MHz to 0.1 Hz with an amplitude of 10 mV at open circuit voltage (OCV).

3. Results and Discussion

3.1. Powder Characterization

Pure LBM exhibits a mixed cubic and hexagonal perovskite phases (Fig. 1a). The hexagonal phase is attributed to the formation of BaMnO$_{3-δ}$ (JCPDS70-3616), which is usually observed in LBM synthesized in an oxidizing atmosphere due to the preferable high oxidation state of Mn$^{4+}$. The Rietveld refinement of the XRD pattern of LBM is shown in Fig. S1, and the calculated lattice parameters are listed in Table S1. No phase transition is observed when Mn is partially substituted by Co and Fe.
Fig. 1. XRD patterns of various anode powders (a) before and (b) after reduction. HRTEM images and corresponding FFT patterns of (c) fresh LBMFC-2 and (d) A-site ordered D-LBMFC-2 powders. The yellow, red and green spheres in the insets represent Ba, La, and Mn/Fe/Co atoms, respectively.

The hexagonal phase disappears after the LBM is reduced in 5% H$_2$-95% Ar at 850 °C for 5 h (Fig. 1b). The Rietveld refinement of the XRD result of D-LBM (Fig. S2) confirms a tetragonal structure, space group $P4/mmm$ with $a = b = 3.91314$ Å and $c = 7.80974$ Å (Table S1), implying an A-site layered double-perovskite structure. The formation of the layered structure with the [LaO$_{δ}$-MnO$_2$-BaO-MnO$_2$-LaO$_{δ}$] series along the $c$ axis and the lack of oxygen specifically in the LaO$_{δ}$ layers.
are due to the general preference of the smaller La$^{3+}$ ions, which are 12-coordinated in the unreduced perovskite, to take eight-fold coordination accompanied with the loss of lattice oxygen.\textsuperscript{54} The main structure of the anode is maintained after the doping of Fe and Co. The HRTEM image and the fast Fourier transformation (FFT) analysis result of LBMFC-2 reveal a lattice space of 0.39 nm (Fig. 1c), consistent with (0 0 1) planes of the cubic structure (space group \textit{Pm}-\textit{3m}) determined by the Rietveld refinement of the XRD result (Fig. S3, Table S1). The HRTEM and FFT results of D-LBMFC-2 show a lattice space of 0.78 nm (Fig. 1d), corresponding to the lattice constant of (0 0 1) planes (space group \textit{P4/mmm}) along the \textit{c} axis (Fig. S4, Table S1). Meanwhile, (0 0 2) planes along the \textit{c} direction with a lattice space of 0.39 nm are also observed in the FFT result of D-LBMFC-2, demonstrating that D-LBMFC-2 has an A-site ordered layered perovskite structure.

Weak peaks corresponding to MnO phase (JCPDS75-0626) are observed in XRD pattern of D-LBM. Similar phase transition processes and exsolution of MnO are involved in the reduction of Pr$_{0.5}$Ba$_{0.5}$MnO$_{3-\delta}$ and Nd$_{0.5}$Ba$_{0.5}$MnO$_{3-\delta}$.\textsuperscript{34,35,37} The partial substitution of Mn by Fe alone results in the stabilization of the perovskite structure and the suppression of the MnO segregation on the surface during the reduction, while the partial replacement of Mn by Co leads to a more serious decomposition of the perovskite structure (Fig. S5). The peaks of MnO in the XRD patterns of D-LBMFC-1 and D-LBMFC-2 are much weaker than that in D-LBM, proving that the co-doping of Co and Fe suppresses the formation of MnO during the reduction. In the XRD pattern of D-LBMFC-2, besides the characteristic peaks of the double-perovskite structure, a peak at 44.302$^\circ$ is also observed (the zoom-in plot), which corresponds to a lattice parameter of 3.537 Å in the \textit{Fm}-\textit{3m} space group of the exsolved metal (Table S1). Since the lattice parameters of metallic Co (JCPDS 89-4307) and Fe (JCPDS 88-2324) in the \textit{Fm}-\textit{3m} space group are 3.544 and 3.430 Å, respectively, the composition of
the nanoparticles exsolved is approximately Co$_{0.94}$Fe$_{0.06}$.

There is no noticeable peak of Co-Fe alloy in the XRD pattern of D-LBMFC-1 probably due to its low amount.

It is well known that the exsolution ability of Fe is highly influenced by cations at A and B sites in the perovskite. For instance, Fe in single perovskite oxides such as La$_{1-x}$Sr$_x$FeO$_{3-\delta}$ is liable to be reduced, resulting in the decomposition of the perovskite structure. On the other hand, Fe cannot exsolve from double perovskites such as PrBaMn$_{1.7}$Fe$_{0.3}$O$_{5+\delta}$ and PrBa(Fe$_{0.8}$Sc$_{0.2}$)$_2$O$_{5+\delta}$ during reduction. The density functional calculation results also reveal that the co-segregation energy of Fe-V is higher than those of Co-V and Mn-V in the doped PrBaMn$_2$O$_{5+\delta}$, which hinders the exsolution of metallic Fe nanoparticles on the surface. However, the co-exsolution of Co$_{1-x}$Fe$_x$ and Ni$_{1-x}$Fe$_x$ alloys have been reported from a number of perovskites such as (La$_{0.7}$Sr$_{0.3}$)(Cr$_{0.85}$Ni$_{0.125}$Fe$_{0.0375}$)O$_{3-x}$, Pr$_{0.4}$Sr$_{0.4}$Co$_{0.2}$Fe$_{0.7}$Nb$_{0.1}$O$_{3-\delta}$, and Sr$_2$FeMo$_{0.65}$Ni$_{0.35}$O$_{6-\delta}$. Since Co is more reducible than Fe, the atom ratio of Co:Fe in the exsolved alloy is much higher than that in the bulk perovskite in most cases. A further increase of the substitute degree, e.g. La$_{0.5}$Ba$_{0.5}$Mn$_{0.7}$Fe$_{0.15}$Co$_{0.15}$O$_{5-\delta}$ (LBMFC-3), brings about the destruction of the perovskite structure (Fig. S6).

The TGA results reveal the phase transition and the loss of lattice oxygen processes in various samples during the reduction (Fig. 2). In order to eliminate the interference of adsorbed water, the TGA curves all start from 250 °C. The quick decrease of the weight between 300 and 500 °C (Stage 1) indicates the rapid formation of oxygen vacancy accompanied with the phase change. At the same temperature, the loss of weight increases with the increase of incorporating amount, indicating that the doping increases the lability of oxygen in the perovskite. The following decrease in weight at a much lower rate between 500 and 750 °C (Stage 2) corresponds to the partial removal of lattice oxygen atoms strongly bonded with the cations in the perovskite. Sengodan et al. observed
a similar weight loss process during the reduction of Pr$_{0.5}$Ba$_{0.5}$MnO$_3$ between 400-800 °C and demonstrated the phase change and the formation of the layered perovskite structure by in situ XRD test. Further increase of the temperature leads to a weight loss at a high rate (Stage 3), which is attributed to the loss of oxygen atoms bonded with B site cations, resulting in the co-segregation and exsolution of MnO and Co-Fe alloy on the surface as shown in the XRD results.\textsuperscript{36, 39} A slow weight decrease followed by a quasi-stable state is observed during the prolonged reduction process at 850 °C for 5 h (Stage 4), indicating a completion of reduction and exsolution.\textsuperscript{39} The weight loss increases with the rise of the substitute degree, implying more oxygen vacancies and exsolved metallic particles. Besides, the weight loss of Fe-doped LBM is similar to that of pure LBM and much lower than that of Co-doped LBM (Fig. S7), further confirming the higher reduction stability of Fe than that of Co, which is consistent with the XRD results (Fig. 1 and Fig. S5).

\textbf{Fig. 2.} TGA results of various samples in 5% H$_2$-95% Ar.
**Fig. 3.** Images of D-LBMFC-2 powder. (a) STEM image and the corresponding EDX elemental mappings; (b) TEM and HAADF-STEM images of exsolved nanoparticles with corresponding EDX elemental mapping profile and (c) HRTEM image of an exsolved nanoparticle.

The STEM image with the EDX elemental mapping of D-LBMDC-2 is shown in Fig. 3a. La, Ba, Mn, Fe and O all distribute homogeneously, while the segregation of Co is observed clearly. The HRTEM image of the Co-enriched area in D-LBMFC-2 shows the exsolution of nanoparticles with a core-shell structure, which are partially embedded in the parent perovskite (Fig. 3b). The HAADF-STEM images coupled with EDX element mapping confirm the uniform distribution of Mn, Fe and O in the parent perovskite, while the concentration of Co near the surface of the perovskite is negligible, indicating that most of surface Co cations are reduced and exsolved. The atom ratios of Co:Fe:O are 0.785:0.078:0.137 in the center (Area A) and 0.455:0.030:0.515 at the edge (Area B) of the exsolved nanoparticle, which are calculated based on the EDX elemental mapping results. The ratio between Co and Fe is approximately 0.94:0.06, which is in accordance with the XRD result. A more obvious core-shell structure of the exsolved nanoparticle is shown in Fig. 3c. The diameter of the core is 30-40 nm, and the thickness of the shell is about 5 nm. The interplanar spacing of 0.202 nm of the core corresponds to the (1 1 1) crystal planes of Co$_{0.94}$Fe$_{0.06}$ alloy, while the spacing of 0.284 nm of the shell is consistent with the (2 2 0) planes of Co-rich (Co, Fe)$_3$O$_4$. Therefore, the exsolved nanoparticles should exhibit a metal-oxide core-shell structure, and the oxygen in the center of the EDX element mapping profile can be explained by the two-dimensional feature of the TEM result.

The core-shell structure of the exsolved Co$_{1-x}$Fe$_x$ and Co$_{1-x}$Ni$_x$ particles have been observed in many research works. However, the formation mechanism of the oxide shell has not been well
explained. Bulk CoO is not thermodynamically stable at 850 °C when the $P_{O2}$ is lower than $10^{-16}$ atm. Nonetheless, the reduction of CoO nanoparticles is highly influenced by the supporter. Generally, CoO nanoparticles which interact strongly with the supporter are less reducible.\textsuperscript{63-65} Meanwhile, the smaller Co particles with more surface contact with the supporter have a lower reducibility. Therefore, the existence of the oxide shell in the 5% H\textsubscript{2}-95% Ar ($P_{O2} \sim 10^{-23}$-$10^{-24}$ atm at 850 °C) is reasonable since the exsolved nanoparticles interact strongly with the perovskite supporter. To further verify this idea, LBMFC-2 was reduced in a less reductive 97% H\textsubscript{2}-3% H\textsubscript{2}O atmosphere ($P_{O2} \sim 10^{-21}$ atm at 850 °C), and the thickness of the oxide shell increases to about 10 nm (Fig. S8). The thickness of the shell is closely related to the partial pressure of O\textsubscript{2} in the reducing atmosphere, confirming that it is formed during the reduction process.

Fig. S9 shows H\textsubscript{2}-TPR profiles of LBM and LBMFC-2 powders. LBM presents a hydrogen consumption peak at around 365 °C. With the doping of Fe and Co, the hydrogen consumption peak shifts to a lower temperature at about 349 °C, implying a reduced metal-oxygen bond energy in the perovskite due to the higher electronegativities of Fe (1.83) and Co (1.88) than that of Mn (1.55),\textsuperscript{66} which is in accordance with the TGA results (Fig. 2). The reduction temperatures of the anode materials are much lower than those of doped and undoped Pr\textsubscript{0.5}Ba\textsubscript{0.5}MnO\textsubscript{3-δ}.\textsuperscript{38} The lower reduction temperature indicates more labile oxygen, which is expected to modify the redox capacity and facilitate the formation of oxygen vacancies. That is further proved by the O 1s XPS results (Fig. S10 and Table S2). With the increase of Fe and Co in the reduced samples, the content of lattice oxygen decreases, while that of adsorbed oxygen species rises. The surface oxygen species are mainly adsorbed on the oxygen vacancies and would be desorbed easily at an elevated temperature.\textsuperscript{67, 68} Therefore, a high content of adsorbed oxygen species reflects a large number of oxygen vacancies,
which brings about a high oxygen ionic conductivity and thus accelerates the electrochemical oxidation of the fuels.

3.2. Electrical Conductivity

The conductivities of D-LBM sintered at 950 °C are 5.70 and 0.88 S cm\(^{-1}\) at 850 °C in air and 5% H\(_2\)-95% Ar, respectively (Fig. S11). With the increase of the doping content of Co and Fe, the conductivity of the sample reduces slightly. It is well known that the oxidation of Mn\(^{3+}\) to Mn\(^{4+}\) is the main origin of the electronic conductivity of manganate perovskites.\(^6^9\) The content of Mn\(^{4+}\) in the reduced samples decreases with the increase of Co and Fe (Fig. S12 and Table S3), resulting in a decline of the conductivity. The exsolved Co\(_{0.94}\)Fe\(_{0.06}\) nanoparticles do not contribute much to the conductivity owing to their low content and high dispersion (Fig. 3a), thus not forming a continuous conductive network.

3.3. SOFC Performance

Fig. S13 shows the surface and cross-sectional microstructures of a single cell with the LBMFC-2 anode. The anode layer possesses a porous structure, which provides sufficient channels and surface for the diffusion and adsorption of fuels.\(^7^0\) A good connection between the porous anode layer, the porous LDC interlayer and the dense LSGM electrolyte layer is formed, which would result in a low interfacial resistance. The thicknesses of the LBMFC-2 and LDC layers are 35-36 and 10-11 μm, respectively.

Fig. 4a exhibits \(I-V\) and \(I-P\) characteristics of the single cells with various anodes fed with wet H\(_2\) (\(\sim 3\%\) H\(_2\)O) at 850 °C. The OCVs of the cells are around 1.0-1.1 V. The \(P_{\text{max}}\) of 962, 1241 and 1479 mW cm\(^{-2}\) are achieved by the cells with D-LBM, D-LBMFC-1 and D-LBMFC-2 as the anodes, respectively. The high \(P_{\text{max}}\) of the cell with D-LBMFC-2 anode is attributed to the high catalytic activity of the anode with more active sites of nanoparticles exsolved on its surface. Meanwhile, more
oxygen vacancies and labile oxygen in the perovskite brought by the doping of Co and Fe is another reason for the improved catalytic activity of the anode, which is demonstrated by the XPS and H_{2}-TPR results. However, the cell with D-LBMFC-3 anode shows a $P_{\text{max}}$ of 1272 mW cm$^{-2}$ (Fig. S14), lower than that of the cell with D-LBMFC-2 anode due to the the decomposition of the anode (Fig. S6). The $P_{\text{max}}$ of the cell increases with the increase of the operating temperature. The cell with the D-LBMFC-2 anode exhibits $P_{\text{max}}$ of 210, 383, 653, 970 and 1479 mW cm$^{-2}$ with wet H$_2$ as fuel at 650, 700, 750, 800 and 850 °C, respectively (Fig. 4b). The performances of the cells in this work are among the best in those of the cells with a perovskite anode and a similar configuration using H$_2$ as fuel (Fig. 4c and Table S4).
**Fig. 4.** *I-V* and *I-P* curves of (a) single cells with different anodes at 850 °C and (b) single cell with D-LBMFC-2 anode at various temperatures with wet H₂ as fuel; (c) Comparison of the $P_{\text{max}}$ of single cells with various high-performance anodes at 850 °C.²⁵, ³⁴, ³⁸, ⁵⁹, ⁶⁸, ⁷¹-⁷⁴ All of the anode layers in (c) were screen-printed on the electrolyte layers. The thicknesses of the anode layers were generally 30-40 μm, which were sintered at 950-1050 °C.

When the fuel is switched to wet CH₄ (~3% H₂O), the OCVs of the cells decrease to 0.85-0.95 V at 850 °C (Fig. 5a) because the electrooxidation of CH₄ is much more difficult than that of H₂.⁷⁵ The $P_{\text{max}}$ of the cells with D-LBM, D-LBMFC-1 and D-LBMFC-2 as anodes at 850 °C are 226, 389 and 503 mW cm⁻², respectively. Fig. 5b provides EIS of various cells at 850 °C. The intercepts of the semicircles at high frequency regions on the real axis are usually associated with the ohmic resistances and the arcs are attributed to the polarization of the electrodes. The ohmic resistances of all the cells are almost the same since the electric conductivities of the anodes are similar (Fig. S11), while as for polarization resistances, an order of D-LBM > D-LBMFC-1 > D-LBMFC-2 is observed, indicating an improvement of the catalytic activity of the anode towards the electrochemical oxidation of CH₄. With a further increase of the substituent degree of the anode, the $P_{\text{max}}$ of the cell with D-LBMFC-3 anode decreases to 287 mW cm⁻² (Fig. S14).
Fig. 5. (a) $I-V$ and $I-P$ curves and (b) electrochemical impedance spectra of single cells with various anodes at 850 °C with wet CH$_4$ as the fuel.

3.4. Effects of different components of anode

3.4.1. Double-perovskite bulk phase

The cell with D-LBMFC-2 anode exhibits the highest performance in 750-850 °C with both H$_2$ and CH$_4$ fuels (Fig. S15). In order to investigate the effects of each component on the performance of the anode, comparative tests are performed subsequently. Since nearly all of the Fe remains in the parent perovskite while most of the surface Co exsolves (Fig. 3b and Fig. S8), La$_{0.5}$Ba$_{0.5}$Mn$_{0.9}$Fe$_{0.1}$O$_{3-\delta}$ (LBMF-1) and La$_{0.5}$Ba$_{0.5}$Mn$_{0.8}$Fe$_{0.2}$O$_{3-\delta}$ (LBMF-2) were synthesized as anode materials for comparison. The SEM results confirm that no obvious nanoparticle is exsolved on the surface of D-LBMF-2 after reduction (Fig. S16). As shown in Fig. 6, the $P_{\text{max}}$ of the cell with D-LBMF-1 anode reaches 1096 and 277 mW cm$^{-2}$ at 850 °C with wet H$_2$ and wet CH$_4$ as the fuels, respectively, which are higher than those of the cell with D-LBM anode. As mentioned above, the doping of Fe brings about more oxygen vacancies and labile oxygen in the perovskite, resulting in a higher catalytic activity. The $P_{\text{max}}$ is further improved when D-LBMF-2 is used as the anode. It should be mentioned that D-LBMF-1 is not exactly the same as the bulk perovskite of D-LBMFC-2 since Co in the latter
is not entirely exsolved during the reduction. Nonetheless, the results prove that Fe in D-LBM facilitates the electrochemical oxidation of H₂ and CH₄.

**Fig. 6.** *I-V* and *I-P* curves of single cells with various amounts of Fe in anodes at 850 °C fed with (a) wet H₂ and (b) wet CH₄.

### 3.4.2. Metal-oxide core-shell nanoparticles

To study the effect of the exsolved metal-oxide core-shell nanoparticles on the performance of the D-LBMFC-2 anode, equivalent Co (about 2.4 wt%) is added into LBMF-1 through infiltration to form D-LBMF-1/Co for comparison. The infiltration process is introduced in the supporting information (Fig. S17). Unlike the *in situ* exsolved nanoparticles with a core-shell structure, no oxide shell is observed after reduction on the infiltrated particles which adhere to the perovskite more smoothly compared with the exsolved nanoparticles (Fig. S18). It further proves that the oxide shell on the exsolved nanoparticle is formed during reduction, not re-oxidation when exposed to air at room temperature before characterization. As mentioned above, the exsolved nanoparticles partially embedded in the perovskite shows a stronger metal-support interaction than the infiltrated nanoparticles. Therefore, the infiltrated nanoparticles are more reducible. Meanwhile, it is very interesting that Co₁₋ₓFeₓ alloy is formed on the surface of the perovskite (Fig. S18) though only Co is
added through infiltration, indicating the exsolution of Fe during the reduction. In contrast, no Fe is exsolved from D-LBMF-2 without the infiltration of Co (Fig. S16), implying that Co facilitates the exsolution of Fe which is worth further study.

Fig. 7. *I-V* and *I-P* curves of single cells with various anodes fed with (a) wet H₂ and (b) wet CH₄; (c) Chronopotentiometry results of single cells with D-LBMFC-2 and D-LBMF-1/Co anodes fed with wet CH₄ at 850 °C; (d) TGA curves of various anodes after carbon deposition in wet CH₄.

Compared to the cell with D-LBMF-1 anode, the cell with the infiltrated anode exhibits high performances with both H₂ and CH₄ fuels attributed to the additional catalytic function of metallic nanoparticles (Fig. 7). Nonetheless, though the amount of the metal catalyst added through infiltration should be higher than that on the surface of D-LBMFC-2 because of the incomplete exsolution in the
latter anode, the catalytic activity of the infiltrated anode is lower than that of the anode containing exsolved nanoparticles, which is partially due to the sintering of the infiltrated particles at the operating temperature.\textsuperscript{39,76} Meanwhile, it has been reported that Co-CoO\textsubscript{x} core-shell nanoparticles are an excellent catalyst for hydrocarbon oxidation.\textsuperscript{77,78}

The cell with D-LBMFC-2 anode is tested with wet CH\textsubscript{4} as the fuel at 850 °C under an output current density of 100 mA cm\textsuperscript{-2} for 200 h without obvious degradation (Fig. 7c). Compared with other excellent perovskite anode materials reported previously, D-LBMFC-2 shows a first-rate activity and a superior stability with CH\textsubscript{4} as the fuel (Table 1). No carbon is observed on the surface of the anode after the test (Fig. S19). In contrast, the performance of the cell with D-LBMFC-1/Co anode drops quickly during the first 60 h, which is mainly due to carbon deposition on the infiltrated anode. In order to study the coking resistance of the anodes, the powders were treated in wet CH\textsubscript{4} at 850 °C for 5 h, and then the amount of carbon deposited were measured through TGA in air. As shown in Fig. 7d, the weight loss of D-LBMFC-2 and D-LBMF-1/Co above 400 °C could be attributed to the oxidation of carbon. D-LBMF-1 shows the highest resistance to carbon deposition. The weight loss of D-LBMFC-2 and D-LBMF-1/Co are about 0.8 wt.% and 1.5 wt.%, respectively. Fig. 8 shows the morphology of D-LBMFC-2 and D-LBMF-1/Co powders after carbon deposition. No obvious carbon deposit is observed on the exsolved core-shell particles in D-LBMFC-2 (Fig. 8 a, b). On the contrary, the infiltrated nanoparticle in D-LBMF-1/Co is covered by a carbon layer with an average thinkness of about 10 nm (Fig. 8 c, d). The carbon shows a well-ordered structure, indicating a high degree of crystallinity which is difficult to be removed by oxidation. Though Co shows a high catalytic activity for carbon deposition,\textsuperscript{6} the oxide shell covering the exsolved nanoparticles improves the resistance to coking of the anode.\textsuperscript{78,79} Meanwhile, the exsolved nanoparticles are partially embedded in the parent perovskite (Fig. 3c). The strong metal-support interaction provides a promising thermal stability and
a high resistance to carbon deposition of the anode.\textsuperscript{24, 36, 80-82} On the contrary, the infiltrated Co\textsubscript{1-x}Fe\textsubscript{x} nanoparticles with a weaker interaction with the perovskite trend to agglomerate at a high temperature, which might be another reason for the rapid performance degradation of the single cell.

4. Conclusion

In this work, a simple *in situ* strategy is developed toward efficient, stable and nonprecious metal containing composite electrocatalysts for SOFCs. Co and Fe are co-doped into the B sites of La₀.₅Ba₀.₅MnO₃₋δ perovskite which exhibits a cubic-hexagonal mixed structure. An A-site ordered double-perovskite main structure is formed after reduction. During the reduction, Co and Fe exsolve from the bulk phase, and metal-oxide core-shell nanoparticles with an average size of about 50 nm are formed on the surface of the perovskite. The nanoparticles distributed homogeneously on the
surface enhance the catalytic activity of the anode significantly. Meanwhile, the incorporation of Co and Fe introduces more oxygen vacancies into the perovskite, which also accelerates the anodic kinetics. The $P_{\text{max}}$ of the single cell with D-LBMFC-2 anode and 300 μm-thick LSGM electrolyte reaches 210, 383, 653, 970 and 1479 mW cm$^{-2}$ with wet H$_2$ as the fuel at 650, 700, 750, 800 and 850 °C, respectively, outperforming the single cells with similar configurations. The same cell fed with wet methane exhibits a $P_{\text{max}}$ of 503 mW cm$^{-2}$ at 850 °C. Furthermore, the nanoparticles covered by an oxide shell and anchoring firmly on the perovskite exhibit a high stability. The cell displays a stable power output at 850 °C for 200 h with wet methane as the fuel.
