SUMMARY
Electricity consumption data profiles that include details on the consumption can be generated with a bottom-up load models. In these models the load is constructed from elementary load components that can be households or even their individual appliances. In this work a simplified bottom-up model is presented. The model can be used to generate realistic domestic electricity consumption data on an hourly basis from a few up to thousands of households. The model uses input data that is available in public reports and statistics. Two measured data sets from block houses are also applied for statistical analysis, model training, and verification. Our analysis shows that the generated load profiles correlate well with real data. Furthermore, three case studies with generated load data demonstrate some opportunities for appliance level demand side management (DSM). With a mild DSM scheme using cold loads, the daily peak loads can be reduced 7.2% in average. With more severe DSM schemes the peak load at the yearly peak day can be completely leveled with 42% peak reduction and sudden three hour loss of load can be compensated with 61% mean load reduction.

KEY WORDS: bottom-up load model, household appliance, demand side management, electric load

INTRODUCTION
Load data is crucial for planning electricity distribution networks and optimal production capacity. Accurate knowledge of the household consumer loads is important when small scale distributed energy technologies are optimally sized into the local network or local demand side management (DSM) measures are planned. This knowledge is also useful for planning medium and low voltage networks in residential areas.

The data that electric utilities typically have on domestic electricity consumption do not contain much information about its nature. The data is normally aggregated consumption of multiple households without knowledge about the events in individual households. The fluctuation of electricity consumption concerning an individual
household remains unrevealed as well as the division of consumption between different types of household appliances. Nevertheless, detailed knowledge can be produced with simulation models.

The electricity demand models are often applied to forecast the demand at the utility level. Rigorous studies on the topic were conducted already in the 70’s and 80’s, resulting in a large number of forecasting methods as reported by Gross and Galina (1987). A more recent review and classification of the forecasting methods has been given by Alfares and Nazeeruddin (2002), where novel methods including fuzzy logic, genetic algorithms and networks (Hippert et al., 2001) have been included in addition to the conventional econometric models (Pindyck and Rubinfeld, 1997). These kinds of forecasting methods are commonly employed when there is little or no knowledge about the appliance stocks and other grass-root level consumer details (Zarnikau, 2003).

End-use models, an alternative to the conventional demand forecasting, represent a bottom-up demand modeling approach. The accuracy of these models depends very much on the availability of grass-root level consumption details. An ideal case would be when the stock of appliances and their usage patterns in households are known and details about the composition of the load are valued, as in "Capasso model" published by Capasso et al. (1994). On the other hand, a utility level bottom-up method presented by Willis (2002) provides much less details on the individual consumer level, although it shows more details than the typical electric demand forecasting scheme.

A typical limitation for detailed bottom-up methods is an extensive need of data about the consumers or their appliances and the households in general. Usually some part of the data is not easily available. In the Capasso model (Capasso et al. 1994), detailed data is needed about consumer behavior. In addition to the consumer behavior, the Norwegian ERÅD model (Larsen and Nesbakken, 2004) also requires very detailed information about the design of the house in which the household is located. On the other hand, Sanchez et al. (1998) applied in their bottom-up model to large databases with partly incomplete or missing data, therefore compromising the accuracy of their results. In our work the need for detailed data is bypassed by using a representative data sample and statistical averages. The random nature of consumption is generated by using stochastic processes and probability distribution functions as the consumption is generated. But then, appliance ownership and daily usage pattern is determined in a similar manner to the Capasso model. As a result, our work demonstrates that quite detailed and realistic electricity consumption data can be generated using generally available appliance information and consumer statistics. The resulting loss in accuracy is compensated by considerable reduction in the data requirements.

The purpose of this work is to demonstrate an easy-to-use consumer load data model that can be used to generate representative electricity consumption data. The method allows combination of individual household datasets into realistic large scale data including thousands of households. The model is finally verified with real electricity consumption data.
OBSERVATIONS AND HYPOTHESIS ON THE BEHAVIOR OF HOUSEHOLD ELECTRICITY CONSUMPTION DATA

A comprehensive set of domestic consumption data was analyzed in order to understand the fundamental characteristics of household load curves. The data was found to behave periodically on a seasonal, daily and hourly scale as discovered in previous Finnish load research projects (Seppälä, 1996; SLY, 1995) and in European end use measurement campaigns (Sidler, 1996; 2002). Convergence of the mean data with increasing number of households was also observed as suggested by Willis (2002). In addition, the distribution of the daily mean energy use was revealed after having removed the seasonal cyclic behavior from the data.

The domestic consumption data used for prevailing observations composed of two Finnish sets of data. The first set (dataset 1) consisted of hourly data from a total of 702 households during the 365 days in the year 2002. The second set (dataset 2) consists of hourly data from totally 1,082 households during 143 days from September 2002 to January 2003, including also the households in the first dataset during that period. The dataset 2 is applied only in the analysis of the coincidental nature of the data, providing the increased number of households for better statistics. The datasets are composed of electricity measurements of complete blocks of flats excluding the electricity consumption not directly used inside the apartments. The blocks have between 27 and 74 apartments whose data consisted mainly of appliances and lighting. Heavy electric heating loads such as space heating or cooling, water boilers or individual saunas were absent.

The daily electricity consumption on a yearly level is often dependent on external variables such as the mean outside temperature and daily daylight hours that typically follow similar patterns over successive years. Due to the northern location this shape becomes often sinusoidal for Finnish conditions (Haapakoski and Ruska, 1998; SLY, 1988). This is explained by the lack of summer time cooling loads, strong seasonal variation in the daylight hours and increased use of domestic appliances in the cold season (Haapakoski and Ruska, 1998). The daily electricity consumption in the first dataset is shown in Figure 1a with a sinusoidal mean curve that models the seasonal variation.

The hourly fluctuation of domestic loads results from the combined effect of consumer availability and activity level (Capasso et al., 1994). Thus the mean daytime consumption during workdays is typically lower than that in the weekends, and in the evening the consumption is somewhat higher compared to the weekend evenings. This is also observed in our data as presented in the Figure 1b. The left side of the load curve presents the mean hourly consumption levels for an average weekday and the right side for the average weekend day. In the datasets, the mean daily consumption during weekdays is significantly lower than the weekend which is characteristic to Finnish load curves for blocks of flats (Adato, 1992).

At individual household level the electricity load curves vary much. The aggregated fluctuation smoothens out and approaches the mean consumption curve when the number of households included in the total load curve is increasing. The coincidental nature of the household loads and their smoothing has been discussed in detail by Willis (2002). In order to measure the smoothing effect for increasing amounts of household
loads, an error sum \( \sum |E_i - \bar{E}_i| \) was calculated over the hourly power demand data. In the sum \( E_i \) is hourly power demand per household and \( \bar{E}_i \) is mean hourly power demand per household for all the households in the sample while \( i \) is index for the hours. Figure 1c shows, when using the log-log scale, how the error sum decreases almost linearly against the number of households using the dataset 2 covering 143 days of data. The mean power demand was computed including all 1082 households in the dataset.

Regardless of the number of similar household loads summed up, some variation remains in the mean daily energy consumption. The variation remains even when seasonal differences and differences between weekdays and weekend days have been compensated. This is partly due to a strong correlation between some loads and daily outside temperature fluctuations, such as heating or air conditioning (de Dear and Hart, 2002) that are not present in our load. It is also partly due to correlated social behavior caused by such phenomena as local weather and local, national or international events. For example, television programs and commercial breaks in them make variations observed in the national network (Bunn and Seigal, 1983). Such a level of details is not considered in our model, although the daily level of variation is included.

As the mean seasonal variations are excluded from the daily mean data, only daily fluctuations from correlated social behavior and uncorrelated random fluctuations remain. In our datasets long term changes in mean temperature has been included into the seasonal variations. As a result, temporal effects from short term weather fluctuation effecting lighting and washing needs as well as entertainment use remain accompanied by the fluctuations caused by the social behavior. Furthermore, a significant part of these effects influences all local households simultaneously. We assume this to be the most significant cause of variations in the mean daily electricity consumption. These effects will typically appear regardless of the number of locally distributed households.

The distribution of the compensated mean daily electricity consumption of our dataset 1 with 702 households is shown in Figure 1d. There we have removed seasonal effects as well as the mean differences between weekdays and weekend days. The bell curve shown is a normally distributed density function. It can be concluded that the distribution of the compensated mean daily electricity consumption is approximately normal.

**MATHEMATICAL MODEL FOR HOUSEHOLD ELECTRICITY CONSUMPTION**

Based on the observations above, we propose a two component bottom-up model for household electricity consumption. The structure of the model is given in Figure 2. The first part of the model (I) defines the general fluctuation of diurnal consumption levels and separate appliance stocks for each household. The second part (II) composes of the main procedures and simulates separately the use of each appliance in the each household. In general, any reference to "one appliance" in the model can refer to an individual appliance or, a group of appliances in the household.

In the first part of the model the fluctuation of diurnal consumption levels is defined. This is achieved by determining the daily values of social random factor \( P_{social} \). The best fitting probability density function and standard deviation for \( P_{social} \) are preferably
defined from a data sample. An example of the distribution of daily energy consumption can be seen in Figure 1d, which corresponds to the distribution of social random factor $P_{social}$. The daily values of social random factor are same to all of the modeled households.

The procedures in the first part of the model are repeated for all household appliances in each of the households. The sets of appliances used are defined statistically. Table 1 shows an example of the mean saturation levels for selected appliances in all Finnish households (SF, 2003). The kind of statistical saturation levels are available for many countries, e.g. in the public statistics of references (Mansouri et al., 1996; SF, 2003; SS, 2002; FSO, 2004). When these saturation levels are applied as availability probabilities each household is defined with a unique set of appliances. This also makes the availability statistics to become coherent with the original one when a large number of households are considered.

The second part of the model (II) simulates the temporal electricity consumption profile of each individual appliance of each household separately. The electricity consumption of an appliance is based on its consumption cycle. On the other hand, the cycle is initiated based on its starting probability that is defined by the starting probability function $P_{start}$.

$$P_{start}(A, W, Δt_{comp}, σ_{flat}, h, d) = P_{season}(A, W) \cdot P_{hour}(A, h, d) \cdot f(A, d) \cdot P_{step}(Δt_{comp}) \cdot P_{social}(σ_{flat})$$

(1)

where

- $P_{season}$ = seasonal probability factor, models the seasonal changes,
- $P_{hour}$ = hourly probability factor, models the activity levels during the day,
- $P_{step}$ = step size scaling factor, scales the probabilities according to $Δt_{comp}$,
- $P_{social}$ = social random factor, models the weather and social factors influencing the communal behavior,
- $f$ = mean daily starting frequency, models the mean frequency of use for an appliance [1/day],
- $A$ = appliance or group of appliances,
- $h$ = hour of the day,
- $d$ = day of the week,
- $W$ = week of the year,
- $Δt_{comp}$ = computational time step [s or min],
- $σ_{flat}$ = standard deviation for $P_{social}$.

$P_{start}$ is defined for each time step $Δt_{comp}$ and it receives a value between 0 and 1. When the appliance is off, the turning on is checked using the probability $P_{start}$. Starting occurs when $P_{start}$ is larger than a random number between 0 and 1. Then the consumption cycle of the appliance will be added to its total load curve of the household. When the time of the on-cycle is reached ($t = t_{start} + t_{cycle}$) the appliance is turned off again and the checking for starting the appliance again will continue. For cumulative appliances, the starting checks will be done during the time the appliance is already on and simultaneously multiple similar appliances can be on (as for lighting). If an appliance
has standby electricity use, it will be added to the whole load curve. Some additional computational characteristics for parameters of starting probability function \( P_{\text{start}} \) are shown in Appendix A.

The input for the second part (II) of the model includes two kinds of parameters. Firstly, the weekly seasonal probability factors \( P_{\text{season}} \) together with the hourly probability factors \( P_{\text{hour}} \) for weekdays and weekend days constitute the probability factors in the model. Secondly, standby consumption and consumption cycle data with mean starting frequencies for each appliance form the constant parameters in the model. The weekly seasonal probability factor \( P_{\text{season}} \) is easiest to define from a measured data sample. The hourly probability factor \( P_{\text{hour}} \) is defined for each hour of a working day and a weekend day. This kind of data is quite readily available, but sometimes without separating between weekdays and weekend days (Ruska and Haapakoski, 1998; Sidler, 1996; 2002).

The active and standby consumption parameters of an appliance are connected through their yearly energy consumption as below.

\[
E_{\text{yearly}} = \left(3600 \cdot 24 \cdot \frac{E_{\text{standby}}}{\text{day}} + \sum_{n=1}^{n_{\text{cycle}}} E_{\text{cycle,n}} \cdot t_{\text{cycle,n}}\right) \cdot \frac{365}{3.6 \cdot 10^6} \cdot \frac{\text{day} \cdot \text{kWh}}{\text{W} \cdot \text{s}} \quad (2)
\]

where

- \( E_{\text{yearly}} \) = mean energy consumption per year [kWh],
- \( E_{\text{standby}} \) = standby consumption level [W],
- \( E_{\text{cycle,n}} \) = power level on step \( n \) of the mean consumption cycle [W],
- \( t_{\text{cycle,n}} \) = length of step \( n \) on the mean consumption cycle [s],
- \( n_{\text{cycle}} \) = number of steps on the mean consumption cycle.

If standby consumption level or the parameters for active consumption are known for an appliance, the mean energy consumption for the remaining part can be estimated by subtracting from the yearly energy \( E_{\text{yearly}} \). Additionally, the mean daily starting frequency \( f \) or total energy of the mean consumption cycle can be determined if one of them is defined.

Combining data from multiple sources may be needed to get reasonable estimates for both starting frequencies and consumption cycle parameters. These sources can include total yearly consumption with mean daily consumption profiles (Ruska and Haapakoski, 1998; Sidler, 1996; 2002) or just the yearly electricity consumption (Mansouri et al., 1996; Nutek, 1994; SLY, 1995). Also typical power levels of household appliances are available, partly as they are crucial for some of the popular non-intrusive load monitoring methods (Cole and Albicki, 1998; Hart, 1992; Pihala, 1998; Rissanen, 1998; Sultanem, 1991; Wood and Newborough, 2003). The standby consumption levels are available at multiple sources (Meier et al., 2004; Rosen and Meier, 2000; Ross and Meier, 2002; Sidler, 1996; 2002).

Some calibration on the input values may be needed for good performance, which is typical with bottom up models (Larsen and Nesbakken, 2004). In our case this is mostly
due to the difference between the kind of households / appliances behind the input data and the kind of data the model is supposed to generate.

**A GENERATED ELECTRIC LOAD PROFILE WITH VERIFICATION**

Using the model described above, a large domestic electricity consumption dataset has been generated applying the procedure in Figure 2. The data set composes of 10,000 households with consumption data for one full year for each individual household. The households are in blocks of flats with no heavy electric heating loads like space heating. The fractional household electricity consumption of different groups of appliances is based on an example in reference (Adato, 2004) and it is presented in Table 2.

The appliance saturation data was mostly obtained from Statistics Finland (SF 2001a; 2001b; 2003) while the coffee maker saturation was compiled from different sources (Männistö et al., 2003) (Private comm. 20th Nov. 2004 with Päivi Suomalainen, Market Research Manager, Oy Gustav Paulig Ab, Finland). Slight modifications of the data were necessary, as the saturation data was not intended for the targeted household group only but for whole Finland. The original and modified saturation levels are presented in Table 3. The main reasons for reducing the ownership densities is the lower than average income level of the people living in apartments in Finland (SF, 1998) together with the lower appliance densities in households with low income (SF, 2001c; 2002).

The yearly curve fitted to dataset 1 is applied to define the weekly seasonal probability factors $P_{\text{season}}$. The hourly probability factors were fundamentally based on results in (Sidler, 1996; 2003). Reference (Ruska and Haapakoski, 1998) was applied to evaluate the difference in social behavior as well as climate conditions. The distributions used for hourly probability factors can be found in Table B1 in Appendix B. On the other hand, the values for $P_{\text{social}}$ for the first part of the model were defined applying the normal distribution function and standard deviation of dataset 2.

The mean daily starting frequencies, the mean consumption cycle data and standby consumption for each appliance were defined simultaneously, as the values are interconnected. The values used here can be found at Table B2 in Appendix B. The consumption cycles have been based on the report by Rissanen (1998), including the original appliance measurements prepared for the report (Private communication Oct. 2001 with Hannu Pihala, VTT, Finland). The standby rates have been compiled based on four references (Hirvonen and Tuhanen, 2001; Pihala, 2001; Ross and Meier, 2002; Sidler, 1996). The daily starting frequencies have been defined based on the other parameters and the yearly consumption values estimated using references (Nutek, 1994; Sidler, 1996; SLY, 1995), the mean consumption in the targeted data and the fractions shown in Table 2.

In the following, the simulated load is presented using the results from the measured data in Chapter 2 as goal values. The simulated daily energy consumption values are presented in Figure 3a together with the seasonal fit from the original measured data. The mean energy per day per household for the generated data is 5.16 kWh/day, slightly higher than the 5.12 kWh/day for the original data. When the seasonal effects and the differences in the weekends and weekdays are eliminated the statistical distribution of the data can be evaluated. Figure 3d shows the corresponding normal distribution. The
standard deviation at the generated data after compensation is 0.203 kWh/day and 0.196 kWh/day for the original data, respectively.

The mean daily profiles resulting for the generated data are shown in Figure 3b. The similarity of the generated and original data is demonstrated in when the figures 1b and 3b are compared. Their hourly differences are below 3%, with an exception of 5% during some night hours.

The coincidental nature of the simulated data is demonstrated in Figure 3c. The absolute deviation of the data when increasing the number of unit loads in the total load from n=1 to n=1,000 behaves as in Figure 1c for the measured data. For the simulated data, the magnitude of the errors is systematically higher. This is due to such nature of occupant behavior that is not captured by the model.

**APPLICATION OF THE LOAD MODEL TO DSM**

To demonstrate the usefulness of the bottom-up model, we present three Demand Side Management (DSM) cases applying the 10,000 household load data generated by the model in the previous chapters. The household loads can be managed separately thus enabling DSM measures on an individual appliance level simultaneously in several households. Table 2 summarizes how the household load is divided between its major uses.

Two kinds of DSM strategies are considered: shifting of the use to a later time, or, turning off the appliance. To keep the household operational some priorities need to be set up for the use of the appliances. The DSM strategies for the case studies are made following an assumed customer priority. Table 4 summarizes the strategies for all the cases. Only 50% of lighting load in a household is allowed to be managed and the cold appliances can switch off for a maximum time of one hour a time with one hour recovery period in between. For simplicity, the management of appliances is done in groups also shown in Table 4.

In case 1 we consider a mild DSM to measure reduction of the peak load during weekdays throughout the year. By postponing the cold loads (priority 0 loads in Table 2) during the peak consumption, reduction in actual peak loads and the mean peak load can be achieved. The second case applies a more complex overall DSM strategy to shave the highest consumption peak of the year. In this case the loads are regulated according to their priority order, and some compromises in the customer comfort are made. The last case demonstrates the full use of DSM to minimize the customer load in response to a sudden 3 hour black-out in early afternoon.

In case 1 the shift of the load of cold appliances by 1 hour results in a 7.2% reduction in the annual mean peak load. This result is achieved during weekdays without any noticeable inconvenience to the consumers. The resulting load curve during an average weekday is demonstrated in Figure 4, where also the original mean load curve can be seen. The peak reduction remains significantly smaller than the total cold appliance capacity. This is due to the large number of peak load hours, causing only part of the cold appliances to be available for management simultaneously, as the cold loads are postponed only one hour at a time. The result shown in Figure 4 is achieved as 3.1%, 27.6%, 52.9%, 47.1%, and 25.5% of the total cold load capacity is managed during the
corresponding hours between 18 and 23. This way the postponed cold loads from the earlier hours can as well be smoothly managed.

In case 2, loads with priorities from 0 to 4 are controlled. Figure 5 shows the resulting total demand profile during the peak consumption day and during the following day. As a result, the peak value is reduced by 42%. This case violates the consumer comfort by postponing the washing loads between 14 and 23, by cutting the entertainment loads between 17 and 23 as well as by reducing the lighting use by 50% for one hour during the evening in 75% of the households. The postponed loads cause an increase of load between 23 and 5 hours in the off-peak period.

Figure 6 shows the resulting load profile in Case 3, where measures in Table 4 are fully utilized during the black-out. In this case, during the first hour a maximal load reduction is applied. The shifted cold-appliance load hits back on the second hour, while the third hour has again a full load reduction. As a result, the achieved mean load reduction is 61%. If the length of the black-out is known in the beginning of the load management, a smooth load response through stepped cold load monitoring can be achieved, as in case 1.

CONCLUSIONS
A realistic method for generating domestic electricity load profiles at individual household level has been presented. The model is based on a bottom-up approach in which the household load composes individual appliances or appliance groups. The input data of the model was mainly collected from public reports and statistics, although also the detailed appliance consumption data used in the work of Rissanen (1998) was applied. Additionally, two partly overlapping hourly domestic consumption datasets were applied for statistical analysis, model training, and verification.

Consumption data with 10,000 individual households has been generated with the suggested model. The verification applied to the data showed a good agreement between statistical qualities of the measured and the generated consumption data. The generated data has all individual consumption groups form table 2 separately available for every individual household hourly throughout the year.

Three Demand Side Management (DSM) case studies were done applying the separation of the generated consumption data into consumption groups at individual household level. First of the case studies demonstrates, that significant reduction of the daily peak consumption can be achieved by using DSM on the load of cold appliances. The load of cold appliances can partially be shifted off the peak hours without causing any customer inconvenience. The peak reduction could be improved further, if the freezers are available for extra cooling few hours before the peak period, using their thermal capacity this way as an extra storage. This would allow moving of the peak load also before the peak.

The second and third case studies were for an individual control need only. In the second case the highest consumption peak in the generated data was leveled using severe DSM causing inconvenience for the consumers. The third case was similarly a full DSM response to a sudden three hour loss of power. Significant consumption still
remained in the third case due to the cold loads, requiring quite much reserve capacity to take care of it.

The household consumption data generating model could be employed also for different applications. But in industrial use, for example, the gathering of input data might require more effort, as the consumption of industrial equipment is less standard. In our future work, the model will be employed for studies of distributed energy generation systems.
NOMENCLATURE

\( A \) = appliance or group of appliances.
\( d \) = day of the week.
\( \sigma_{flat} \) = standard deviation for \( P_{social} \).
\( E_i \) = hourly power demand per household while \( i \) is index for the hours.
\( \bar{E}_i \) = mean hourly power demand per household for all the households in a sample while \( i \) is index for the hours.
\( E_{yearly} \) = mean energy consumption per year [kWh].
\( \dot{E}_{standby} \) = standby consumption level [W].
\( \dot{E}_{cycle,n} \) = power level on step \( n \) of the mean consumption cycle [W].
\( f \) = mean daily starting frequency, models the mean frequency of use for an appliance [1/day].
\( h \) = hour of the day.
\( n_{cycle} \) = number of steps on the mean consumption cycle.
\( P_{season} \) = seasonal probability factor, models the seasonal changes.
\( P_{hour} \) = hourly probability factor, models the activity levels during the day.
\( P_{step} \) = step size scaling factor, scales the probabilities according to \( \Delta t_{comp} \).
\( P_{social} \) = social random factor, models the weather and social factors influencing the communal behavior.
\( \Delta t_{comp} \) = computational time step [s or min].
\( t_{cycle,n} \) = length of step \( n \) on the mean consumption cycle [s].
\( t_{start} \) = appliance starting time.
\( W \) = week of the year.
APPENDIX A

The probability factors in Equation (1) have the following additional characteristics.

\[ N_{\text{steps}} \cdot P_{\text{step}} = 1.0 \quad \text{when} \quad N_{\text{steps}} = \frac{\Delta t_{\text{comp}}}{60 \text{ min}}, \]

\[
\sum_{h=1}^{24} P_{\text{hour}}(A = A_n, h, d = d_m) = 1.0, \quad \sum_{W=1}^{52} P_{\text{season}}(A, W) = 1.0
\]

\( N_{\text{steps}} \) is the number of computational steps per hour while \( A_n \) and \( d_m \) represent any chosen appliance during any chosen day, correspondingly. As shown below, the mean yearly starting rate can be calculated as the sum over the daily starting frequencies.

\[
N_{\text{year,mean}}(A) = \sum_{W=1}^{52} \sum_{d=1}^{7} \sum_{h=1}^{24} \left\{ P_{\text{appl}}(A, h, d, W, \Delta t_{\text{comp}}, \sigma_{\text{flat}}) \right\} = \\
\sum_{W=1}^{52} P_{\text{season}}(A, W) \cdot \sum_{d=1}^{7} f(A, d) \cdot \sum_{h=1}^{24} P_{\text{hour}}(A, h, d) \cdot \sum_{\text{steps}} P_{\text{step}}(\Delta t_{\text{comp}}) \cdot \left\{ P_{\text{social}}(\sigma_{\text{flat}}) \right\}
\]

\[ \Leftrightarrow N_{\text{year,mean}}(A) = 52 \cdot (5 \cdot f(A, \text{weekday}) + 2 \cdot f(A, \text{weekend day})) \]
APPENDIX B
Details of model input are presented in Tables B1 and B2.

a) Daily electricity consumption for generated dataset. The mean curve from Figure 1 is presented with thick gray line.  
b) Mean hourly consumption curve of a household for weekdays and weekend days for the generated dataset.  
c) Coincidental behavior for generated dataset. The corresponding data from Figure 1 c) is shown with symbol ⊗.  
d) Distribution of the compensated mean daily electricity consumption days for generated dataset. The corresponding normally distributed curve is presented with thick dark line.

Figure 4.  

The mean demand curve for an average weekday after the DSM using the cold load for the management. Mean demand curves without DSM are presented with thick gray lines.

Figure 5.  

Peak demand day of the year and the following day after the DSM measures in case 2. The peak shaving has been only done during the peak conditions. Mean demand curves without DSM are presented with thick gray lines.

Figure 6.  

The resulting demand curve for the case 3 after the maximal DSM. The demand curve without DSM is presented with thick gray line. The second hour peak is due to post postponed cold appliance load during the first managed hour.
Table captions

Table 1. Mean saturation levels for chosen appliances in all Finnish households (SF, 2003a).

Table 2. An example about the division of electric consumption in a three person household living in a block apartment. Three rooms with 75m² total surface area have been assumed. (Adato, 2004)

Table 3. Applied saturation levels for appliances and groups. Column "Orig." has the original values available in the listed references, while column "Applied" presents the corresponding availability probabilities applied in the load model.

Table 4. The applied DSM strategies for appliances and groups in case studies 1-3.

Table B1. Daily starting frequencies, standby loads and consumption cycle information applied in the load model for appliances and groups.

Table B2. Hourly starting probabilities applied in the load model for appliances and groups.
Figure 1.
Figure 2.

1. Setup input data
2. Define daily fluctuations in social random factor
3. Household load curve generation loop [for each household]
4. Data output and verification
5. Define a set of appliances in the household
6. Appliance load curve generation loop [for each appliance]
7. Define hourly power over the total time
8. Sum up the appliance load curves into hh load curve
