Abstract: Thermal stabilities of selected ternary phases of industrial interest in the Ag-Cu-S system have been studied by the calorimetric and electromotive force techniques. The ternary compounds $\text{Ag}_{1.2}\text{Cu}_{0.8}\text{S}$ (mineral mackinstryite) and $\text{AgCuS}$ (mineral stromeyerite) were equilibrated through high-temperature reaction of the pure $\text{Cu}_2\text{S}$ and $\text{Ag}_2\text{S}$ in an inert atmosphere. The synthesized single solid sample constituting the two ternary phases was ground into fine powders and lightly pressed into pellets before calorimetric measurements. An electrochemical cell incorporating the two equilibrated phase and additional $\text{CuS}$ as a cathode material was employed. The measurement results obtained with both techniques were analyzed and thermodynamic properties in the system have been determined and compared with the available literature values. Enthalpy of fusion data of the Ag-richer solid solution ($\text{Ag}_x\text{Cu}_{1-x}\text{S}$) have also been determined directly from the experimental data for the first time. The thermodynamic quantities determined in this work can be used to calculate thermal energy of processes involving the Ag-Cu-S-ternary phases. By applying the obtained results and the critically evaluated literature data, we have developed a thermodynamic database. The self-developed database was combined with the latest pure substances database of the FactSage software package to model the phase diagram of the $\text{Ag}_2\text{S}$-$\text{Cu}_2\text{S}$ system.

Keywords: sulfide; silver; copper; inorganic materials; thermal analysis; thermochemistry; thermal energy; phase diagram

1. Introduction

Today, the complexities and low grade of the available raw materials from ore deposits are challenging the production of high-grade metals by the conventional metallurgical processes. To address this issue, metallurgists are considering alternatives strategies and modify operating flow sheets for processing more complex feedstock in an energy efficient, environmentally friendly and economically sound way. To make the appropriate modifications, accurate knowledge of existing phase relations and their thermal stabilities during the whole metallurgical processes are essential.

Ongoing research and development efforts to advance extraction metallurgy are aiming at (a) efficient utilization of the chemical energy of the concentrate and minimization/elimination of carbon-based fuel consumption, (b) maximum environmental protection and the production of controlled gas with a high content of $\text{SO}_2$, and (c) high recovery of the primary metal and minor metals including the precious metals [1]. The overall result of these efforts will eventually contribute to create adaptive and dynamic metallurgical processes, including roasting as a thermal pretreatment that enriches raw materials and extracts thermal energy. For example, the main steps in the copper production process at the Boliden Rönnskär (Skelleftehamn, Sweden) smelter presented in [2] consist of drying, roasting, smelting, converting and refining. The thermal energy generated mainly
from sulfur containing minerals in the fluidized bed roasting process can be utilized for drying the feed materials.

Copper- and silver-containing sulfide minerals are often found in the complex ore minerals that are available for the base and precious metals extraction. Among the silver-based ternary phases, stromeyerite \((\text{Ag}_{0.9}\text{Cu}_{1.1}\text{S})\) is a relatively common ore mineral in most hydrothermal vein and replacement deposits [3]. Generally, silver is considered as a typical impurity in the sulfide ores for copper extraction. In the ores, it exists as a native silver and as a component of mineral phases [4]. Thus, a significant amount of silver may end up in the primary copper making via pyrometallurgical processing routes. In the high-temperature extraction processes, it is concentrated in the copper phase and subsequently recovered at the electro-refining stages as a byproduct together with the other precious metals [5].

Besides their mineralogical importance in the metal extraction missions, copper and silver halides, chalcogenides, and chalcohalides have attracted attention over the past decades due to their properties to exhibit mixed electronic and ionic conduction [6–9]. Recently, the Ag-Cu-S-ternary phases were observed to exhibit phase transformations due to temperature dependent cationic mobility [10,11]. This unique property, together with their high ionic conductivity \((\lambda)\) following phase transformations, initiated the most recent research activities in the Ag-Cu-S system. For example, the face-centered cubic (FCC) structured \((\text{Cu},\text{Ag})_2\text{S}\) solid solution has been reported to have \(\lambda(573\text{ K}) \approx 2.4\text{ S cm}^{-1}\) [12], and also evaluated to have uncommon optical properties [13]. \(\text{AgCuS}\) belongs to this family and shows several temperature dependent structural transitions and performs \(p-n-p\) type conduction switching coupled with a colossal variation of thermopower in connection with the structural changes [8,11]. These unique properties, generally, make \(\text{Cu-Ag-sulfides}\) candidate inorganic materials for transistors, photovoltaic devices, semiconductor-switches, and temperature-controlled-diodes and transistor devices [14,15].

Inorganic materials research involves the determination of phase transformations, melting, phase equilibria with coexisting phases, and other application-based thermodynamic properties. The availability of these data help to optimize materials processing including extraction and recovery of metals, and from a materials science point of view, the data assist the selection of high-performance and cost-effective materials and enable the optimization of their processing technology [4].

Therefore, well-defined thermodynamic properties of the equilibrium phases in the \(\text{Ag-Cu-S}\) system and modeling of the system have a great fundamental and practical interest in extractive and physical metallurgy.

The experimental results of an electrochemical and calorimetric study on \(\text{Ag}_{0.93}\text{Cu}_{1.07}\text{S}\) (mineral stromeyerite) and the solid solution \((\text{Cu},\text{Ag})_2\text{S}\) in the \(\text{Cu}_2\text{S}\)-rich region, along with thermodynamic considerations, were presented in [4,16]. The present work involves a continuation that follows the previous research and investigates in the \(\text{Ag}_2\text{S}\)-richer region, specifically at the vicinity of 65 wt% \(\text{Ag}_2\text{S}\) in the \(\text{Ag}_2\text{S}-\text{Cu}_2\text{S}\) system, by the means of the simultaneous differential scanning calorimetry (DSC) and thermal gravimetric analysis (TGA) and electromotive force (EMF) techniques. Thus, this experimental work completes the deficiencies in the thermodynamic data of the \(\text{Ag}_2\text{S}\)-rich part of the \(\text{Cu}_2\text{S}-\text{Ag}_2\text{S}\) system. The previous and current experimental data were utilized together with literature data to complete the optimization of the complex phase diagram of the \(\text{Ag}_2\text{S}-\text{Cu}_2\text{S}\) system.

**Literature Data on Phase Equilibria and Thermodynamics in the \(\text{Ag}_2\text{S}-\text{Cu}_2\text{S}\) System**

\(\beta\text{Cu}_2\text{S}\) (monoclinic, mineral low-chalcocite) transforms at 376 K to \(\gamma\text{Cu}_2\text{S}\) (hexagonal, mineral high-chalcocite), which is stable up to 708 K [17]. \(\beta\text{Cu}_2\text{S}\) may dissolve up to 1.87 \(\pm 0.37\) mol\% \(\text{Ag}_2\text{S}\), at 336 K [18]. Thermal stability data for \(\text{Ag}_2\text{S}\) is summarized in [19]. At temperatures < 400 K, three ternary compounds in the Ag-Cu-S system are known to be thermodynamically stable; these are body-centered tetragonal \(\text{Ag}_{1.55}\text{Cu}_{0.45}\text{S}\) (mineral jalpaite), orthorhombic \(\text{Ag}_{1.2}\text{Cu}_{0.8}\text{S}\) (mineral mackinstryite), and orthorhombic \(\text{Ag}_{1-\lambda}\text{Cu}_{1+\lambda}\text{S}\) (mineral stromeyerite) [18,20–25]. All of the ternary compounds exist below
392 K and on the Ag$_2$S-Cu$_2$S tie line [20,21]. Skinner [18] characterized these phases with X-ray diffractometer at elevated temperatures.

Of all the ternary compounds, stromeyerite was reported to exhibit significant compositional range. According to Skinner [18] and Frueh [23], stromeyerite (Ag$_{1-x}$Cu$_{1+x}$S) exhibits extended stoichiometric variation, $0 \leq x \leq 0.1$. The stromeyerite reported in [25], Ag$_{0.89}$Cu$_{1.10}$S, is in the range of the proposed stoichiometric variation. Earlier, we synthesized stromeyerite saturated with Cu$_2$S that has a composition of Ag$_{0.93}$Cu$_{1.07}$S [4]. Stromeyerite with 1:1:1 molar ratio, AgCuS, has been synthesized by [8,11,26], by applying different methods.

At temperatures above 392 K, Cu$_2$S and Ag$_2$S reacts to form three solid solutions of different crustal structures: (Cu,Ag)$_2$S(BCC), (Cu,Ag)$_2$S(HCP) and (Cu,Ag)$_2$S(FCC) [27,28]. Above 363 K, Ag$_{0.93}$Cu$_{1.07}$S restructures as a Cu$_2$S-Ag$_2$S solid solution, i.e., (Cu,Ag)$_2$S(HCP) [20]. The solid solution then becomes a dominant phase together with (Cu,Ag)$_2$S (BCC) [21]. Both the copper- and silver-richer (Cu,Ag)$_2$S (BCC) undergo high-temperature transformation into (Cu,Ag)$_2$S (FCC) [12,20], which has homogeneity regions starting from the pure Ag$_2$S and Cu$_2$S sides [12]. The solidus and liquidus curves of the FCC solid solution were mainly determined by Schwartz [29]. The work of Guin et al. [8] and, recently, Tesfaye et al. [4], confirm that the congruent melting temperature and composition of the FCC solid solution determined by Schwartz [29] is accurate. In the late 1960s and early 1970s, Perrot and Jeannot [30] studied the (Cu,Ag)$_2$S solid solution by means of measuring activities of Ag$_2$S at 790 K, and Werner [31] studied thermodynamic properties of the solid solution at 573 K by the EMF method.

Activities of Ag and Cu were measured in a series of experiments that involved stromeyerite [26], jalpaite [32,33], and mackinstryite [34] on the Ag$_2$S–Cu$_2$S tie line at CuS saturation, by the EMF method. Trots et al. [11] have determined the phase transition temperature of stromeyerite and the melting temperature of the solid solution along the composition AgCuS, by the calorimetric method. Tesfaye et al. [4,16] studied properties of stromeyerite and the solid solution (Cu,Ag)$_2$S at Cu$_2$S saturation by the EMF and differential scanning calorimetry-thermogravimetric analysis (DSC-TGA) methods.

2. Materials and Methods

2.1. Materials Preparation

The chemicals utilized in this study are listed in Table 1 with their purity. The ternary phase assemblage composed of Ag$_{1.2}$Cu$_{0.8}$S and AgCuS were synthesized from fine powders of Ag$_2$S (65 wt%) and Cu$_2$S (35 wt%) specified in Table 1. These fine powders were thoroughly mixed with an agate mortar and pressed into pellets with subsequent sealing in an evacuated fused silica ampoule. Prior to sealing, the ampoule was flushed several times with argon gas. The sample was subjected to a heat-treatment in a chamber furnace (AWF 12/25 type, Lenton, UK) with a stepwise-increasing temperature profile: at 573 K for three days, at 873 K for ten days, and at 1173 K for a few minutes. To avoid thermal shock, buildup of partial pressure (which may result in the breakage of the ampoules), and deposition of materials in other parts of the fused silica ampoules, we have followed a slow heating and cooling rate of 10 K/min.

At the last step, the samples were entirely melted to attain high homogeneity level, then cooled down to 338 K and annealed for three weeks. The material produced was analyzed with a LEO 1450 (Carl Zeiss Microscopy GmbH, Jena, Germany) scanning electron microscope (SEM) coupled with an Oxford Instruments X-Max 50 mm$^2$ (Oxford Instruments plc, Abingdon, Oxfordshire, UK) energy dispersive spectrometer (EDS). The SEM-EDS analysis confirmed the coexistence of two ternary phases, synthetic mackinstryite and stromeyerite. The micrograph of the material synthesized is shown in Figure 1. The equilibrated stromeyerite has an approximate composition corresponding to AgCuS, which is in agreement with the literature data [18], suggesting stromeyerite in equilibrium with mackinstryite to have the Ag/Cu ratio 1. The stromeyerite at Cu$_2$S saturation, synthesized in the previous studies [4,16], had an approximate composition of Ag$_{0.93}$Cu$_{1.07}$S.
The solid electrolyte RbAg$_4$I$_5$ was synthesized by mixing stoichiometric amounts of high purity AgI and Rbl (Table 1) with distilled water to form a dense paste. The mixture was placed in a fused silica crucible and dried in an oven at a slowly increasing temperature. The remaining dry reactants were annealed in a resistance vertical tube furnace (CSC 12/

2.2. Thermal Analysis

Thermal characterization of the synthesized specimen comprised of Ag$_{1.2}$Cu$_{0.8}$S and AgCuS phases was conducted by the DSC-TGA method. A STA-449-F1-Jupiter®—simultaneous DSC-TGA analyzing equipment of the NETZSCH Group (NETZSCH-Gerätebau GmbH, Selb, Germany)—was employed for the experimental runs. The calorimeter was calibrated with the enthalpies of melting and melting temperatures for ultra-pure substances Zn, Sn, Au, In, Al and Bi. From the observed variations during the calibration measurements, the uncertainties for the temperatures and enthalpies of melting were estimated as ±1 K and ±1.2%, respectively.

Figure 2 shows the sample preparation and experimental procedure applied during all experimental runs. More details of the materials and gas used are described in the figure. Prior to each run (for baseline (empty pans), calibration (one pan with sapphire) and sample measurements), the chamber was evacuated and then backfilled with pure argon gas three times. In the initial stage, the furnace was heated to 298 K and kept at this
temperature for ten minutes. Then, the furnace was heated and cooled at the same rate as specified at the bottom right corner of Figure 2. Heat flow and weight losses in all runs were recorded simultaneously.

**Figure 2.** (a) Sample preparation for the differential scanning calorimetry-thermogravimetric analysis (DSC-TGA) measurements, and (b) the two-step experimental procedure in the DSC-TGA measurements.

2.3. Electrochemical Examination

2.3.1. Galvanic Cell Formation and the Experimental Setup

Three essential parts of the galvanic cell, i.e., the electrolyte, the reference electrode, and test electrode, were separately prepared and then assembled together by pressing it into a pellet with a sandwich structure. The solid electrolyte RbAg₄S₅ synthesized was pulverized and utilized freshly in an amount of approximately 2.8 g. A small piece (8 mm × 8 mm) of high purity silver foil with 0.5 mm thickness (Table 1) was cleaned with a polishing paper from possible contaminations at the surface (e.g., oxide films) and utilized freshly. The choice of the pure silver as the reference electrode is due to the choice of Ag⁺ ion conducting electrolyte; other researchers, for example, Schmidt et al. [34], have applied Cu⁺ ion conducting electrolytes and pure copper as a reference electrode. The test electrode comprised of three phases was prepared from highly pure CuS (Table 1) and the synthesized sample containing Ag₁.₂Cu₀.₈S and AgCuS. The total mass of the test electrode was about 2 g. The phases were mixed in the following approximate molar ratio: CuS/Ag₁.₂Cu₀.₈S/AgCuS = 1/4/4, representing the red solid square in Figure 3.

**Figure 3.** A portion of isothermal phase diagram of the ternary Ag-Cu-S system, below 363 K (illustrated based on the information provided in [4]). Notations: S2 is Ag₀.₃₅Cu₁.₀₇S (ortho), S3 is Ag₁.₂Cu₀.₈S (ortho), S4 is Ag₁.₅₃Cu₀.₄₅S (bct), and (x) is composition of the cathode material.
Prior to mixing, the synthesized assemblage of the two ternary phases was pulverized with an agate mortar. The galvanic cell was pressed with a 15 mm diameter mold, starting with the test electrode layer, followed by the electrolyte layer and the reference electrode at the top (Figure 4A). The final pressure applied was about 0.27 GPa. To maintain excellent contacts between the interfaces and equilibrate, the constructed electrochemical cell was thermally treated for a day at a temperature well below the melting point of the electrolyte (400 K) prior to the start of the actual measurement.

Platinum lead wires (Table 1) were connected to the electrodes and the galvanic cell was put into an alumina crucible. The EMF measurements were conducted in a resistance with the test electrode layer, followed by the electrolyte layer and the reference electrode at the top (Figure 4A). The final pressure applied was about 0.27 GPa. To maintain excellent contacts between the interfaces and equilibrate, the constructed electrochemical cell was thermally treated for a day at a temperature well below the melting point of the electrolyte (400 K) prior to the start of the actual measurement.

**Figure 4.** The sandwich structured galvanic cell (A)—freshly prepared, and (B,C)—after the measurement: 1—the test electrode (three phase mixture), 2—the solid electrolyte (RbAg$_4$I$_5$), 3—the reference electrode (Ag foil), 4—the Pt cathode lead wire, and 5—a print of the Pt anode lead wire.

The structure of the electrochemical cell at the beginning of the measurement can be represented by the assemblage (cell I).

Cell I:

$$(-)\text{ Pt} | \text{ Ag} | \text{ RbAg}_4\text{I}_5 | \text{ Ag}_{1.2}\text{Cu}_{0.8}\text{S} + \text{ AgCuS} + \text{ CuS} | \text{ Pt} (+) $$

**Figure 5.** Schematics of the electrochemical setup; 1—vertical resistance furnace, 2—fused silica wok tube, 3—alumina crucible, 4—galvanic cell, 5—Pt anode lead wire, 6—Pt cathode lead wire, 7—upper alumina tube, 8 and 9—Pt100 resistance thermometers, 10—lower alumina tube, 11—alumina disc.
2.3.2. Measuring Devices and the Procedure

The Pt lead wires were connected to an electrometer Keithley 6517B (Keithley Instruments, Inc., Cleveland, OH, USA) with a high input impedance to measure the EMF of the galvanic cell. The high input impedance of the electrometer for open cell voltage measurements was $2 \times 10^{14}$ Ω. It allows the galvanic cell to function in a reversible way without any external current flowing [36].

Calibrated Pt100 resistance thermometers (TERMOTECH SRL, Vigevano, Pavia, Italy), with a tolerance class B 1/10 Din, SKS-Group, were connected to Keithley 2000 multimeters. The temperature was measured from above and from below of the galvanic cell. The galvanic cell was allocated into the isothermal zone of the furnace with the least temperature gradient by adjusting the cell position along the furnace height. The temperature difference between the two thermometers was less than 0.3 K during the entire experiment. Thus, any possible thermoelectric effects in the cell EMF were negligible.

The values of temperature and EMF were measured simultaneously and recorded with a computer with a rate of one measurement point per minute. The measurement was conducted at a constant temperature until equilibrium was attained. The equilibration criterion was behavior of the measured EMF as a function of time. When the EMF was asymptotically approaching a certain value and its changes within the last 24 h were less than 0.1 mV or it was fluctuating in the vicinity of a certain value for the same time, it was considered as an equilibrium. Equilibration time varied from 36 h to three weeks. Once the cell was equilibrated, the temperature was changed and equilibration started at a new temperature. The measurements were conducted through heating and cooling cycles to confirm reversibility and repeatability of the measurements. The measurements were conducted in the temperature range from 308 to 402 K.

3. Thermodynamic Optimization

By combining the critically reviewed literature data and experimental data in this work, we developed a database that enables thermodynamic calculations in the Ag$_2$S-Cu$_2$S system. The optimization was done by combining our own database and the SGPS–SGTE pure substances database, which is compiled by the Scientific Group Thermodata Europe [37]. The calculations and assessments were performed using the FactSage 7.1 software package [38]. Details on the optimization method were described in our recent openly accessible article [39].

4. Results and Discussion

4.1. DSC Measurement Data

The DSC-TGA measurements were conducted for the equilibrated two-phase sample (Ag$_{1.2}$Cu$_{0.8}$S and AgCuS) in this work. The dashed straight line in Figure 6 at ~65 wt% Ag$_2$S indicates the composition and temperature range of the DSC-TGA measurement.

The results obtained after heating from 298 to 973 K are presented in Figure 7. On the heating DSC curve, phase transitions and melting temperatures appeared as endothermic peaks. The hatched area of the melting peak depicted in Figure 7 yielded enthalpy of fusion of the Ag-richer solid solution (Ag,Cu)$_2$S.

Temperatures of phase transformation and melting determined by the DSC method are compiled in Table 2, in comparison with the values reported in the published literature. As the TGA curves in Figure 7 show, mass loss of the sample upon heating and cooling is negligible. Therefore, the overall chemical composition of the analyzed sample was assumed to be constant during the thermal cycles, as indicated in Figure 6, i.e., along the 65 wt% Ag$_2$S (the red dashed line).
The observed onset temperatures at 363.7 ± 1, 402.5 ± 1 and 922.2 ± 1 K indicated in Figure 7 can be interpreted as the melting temperature of the Ag2S-richer solid solution. The hatched area of the melting peak depicted in Figure 7 yielded enthalpy of fusion of the Ag-richer solid solution (Ag,Cu)2S.

The differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA) curves for the synthesized two phases assemblage (Ag1.2Cu0.8S and AgCuS). The red and blue curves represent heating and cooling, respectively. The dashed curves are TGA vs. T and solid curves are DSC vs. T.

The observed onset temperatures at 363.7 ± 1, 402.5 ± 1 and 922.2 ± 1 K indicated in Figure 7 correspond well with the phase transition and liquidus temperatures reported in the literature. As can be seen in Table 2, the onset temperature observed at 363.7 K is in good agreement with the stromeyerite transformation into the solid solution (Ag,Cu)$_2$S(HCP), as reported by [4,6,11]. Despite the compositional differences that can alter thermodynamic properties, the transformation temperature presented in the proposed phase diagram of Chang et al. [20] is lower by up to 10 K than our measurement and the recent literature values of [4,6,11]. The onset temperature observed at 402.5 ± 1 K corresponds with the reported temperature of decomposition of stromeyerite into two phases at 399 K [11]. The slight temperature differences could be due to compositional variation as depicted in Table 2. Precisely, this phase transition temperature at 402.5 K, which comes after Ag$_{0.93}$Cu$_{1.07}$S transition to (Ag,Cu)$_2$S(HCP) at 364 K (Table 2), represents the phase transition from Ag$_{1.2}$Cu$_{0.8}$S to Ag$_{1.35}$Cu$_{0.45}$S in the presence of (Ag,Cu)$_2$S(HCP).

The onset temperature 922.3 K of the sharp peak on the heating curve shown in Figure 7 can be interpreted as the melting temperature of the Ag$_2$S-richer solid solution (Ag,Cu)$_2$S (FCC). According to the proposed phase diagram of Chang et al. [20], at the same composition of the experimental runs, the melting temperature of the solid solution is higher by about 15 K. In the previous work [4], melting temperature of the Cu$_2$S-richer solid solution (Cu,Ag)$_2$S (FCC) was determined to be 944 ± 1 K. The temperature difference between the Ag$_2$S- and Cu$_2$S-richer solid solutions suggest that adding a certain amount of Ag$_2$S to the system tend to decrease melt formation temperatures.

Enthalpy of fusion for the Ag-richer solid solution with Ag/Cu ratio of ~1.2 was determined from the DSC measurements and presented in Equation (1) with its corresponding liquidus temperature. $\Delta_{\text{melt}}H$ value for the Ag-richer solid solution is lower than that of the Cu-richer solid solution determined in our previous work [4], Equation (2), by about ~1.5 kJ·mol$^{-1}$. The error values indicated in Equations (1) and (2) for both temperatures and enthalpies are average accuracies calculated during the temperature and sensitivity calibrations, as described in the Experimental section. Decimals were rounded to the next whole number.

$$(\text{Ag}_{1.09}\text{Cu}_{0.91})\text{S(s.s., FCC)} \rightarrow \text{L} \quad \Delta_{\text{melt}}H = 4.1 \pm 1 \text{ kJ·mol}^{-1}, \text{at } T_{\text{melt}} = 922.3 \pm 1 \text{ K} \quad (1)$$

$$(\text{Ag}_{0.92}\text{Cu}_{1.08})\text{S(s.s., FCC)} \rightarrow \text{L} \quad \Delta_{\text{melt}}H = 5.6 \pm 1 \text{ kJ·mol}^{-1}, \text{at } T_{\text{melt}} = 943.9 \pm 1 \text{ K} \quad (2)$$

4.2. EMF Measurement Data Analysis

The measured EMF values with electrochemical cell I as a function of temperature are presented in Figure 8. The average temperatures of those measured at both ends of the electrochemical cells were considered in deriving the thermodynamic data. The parasitic cell potential contributions to the cell EMF, resulting from the presence of the slight temperature gradients and contact potential differences, were obtained with the symmetric cells and eliminated from the EMF values at each temperature.

In the range of the experimental temperature, 308–402 K, EMF values increased with heating linearly. Thus, for the solid-state reactions in different thermal stability regions, the temperature dependent EMF values can be expressed by the typical linear equation $E = a + b·T$ [4,16]. In accordance with this equation, the dependencies of the measured EMF
values of electrochemical cell I on temperature, in two different temperature ranges, are expressed as Equations (3) and (4).

\[
E(V) = 0.03700 + 0.24100 \cdot T(K) \cdot 10^{-3} \quad (308 < T/K < 367)
\]

\[
E(V) = -0.04134 + 0.45000 \cdot T(K) \cdot 10^{-3} \quad (382 < T/K < 402)
\]

When equilibrium is attained, the transfer of the Ag+ ion at the interface into the cathode or the overall reaction of cell I can be represented by the virtual electrochemical cell reactions (5) and (6). Compositions of the solid phases are according to the composition of the cathode materials at the beginning of the measurements.

\[
19/20Ag + 19/20CuS + 1/20Ag_{1.2}Cu_{0.8}S = Ag_{1.01}Cu_{0.99}S \quad (5)
\]

\[
19/20Ag + 19/20CuS + 1/20Ag_{1.2}Cu_{0.8}S = (Ag,Cu)_2S(HCP) \quad (6)
\]

Solving Equations (3) and (4) simultaneously, the phase transformation temperature over the experimental temperature range 308–402 K were found to be \( T = 375 \pm 1 \) K. This temperature is about 10 K higher than the value obtained with the DSC technique and the literature values for \( Ag_{0.93}Cu_{1.07}S = (Ag,Cu)_2S(HCP) \) phase transition temperature, 361–365 K [4,6,11]. The phase transition temperature differences between the result obtained with the EMF method and the literature value could be attributed to the compositional differences, as the solid solution forms in the electrochemical cell in equilibrium with CuS.

Gibbs Energies of Formation (\( \Delta_f G^\circ \))

Difference in the chemical potential of Ag in the anode and cathode materials of the electrochemical cells I (\( \Delta \mu_{Ag} \)) is directly proportional to the generated EMF values, at an isotherm equilibrium. Thus, from the obtained EMF values as a function of temperature, Gibbs energies, enthalpies, and entropies of reactions (5) and (6) can be determined by applying the fundamental thermodynamic Equation (7) [4].

\[
\Delta_f G^\circ(T) = -z \cdot F \cdot E(T),
\]
where \( z \) is the electrons involved in the electrochemical cell reaction, which is 0.95 (19/20 moles) in reactions (5) and (6), the Faraday constant \( F \) is 96,485.33 C·mol\(^{-1}\) [40], and the EMF of the electrochemical cell \( E \) is in V. The Gibbs energies of the virtual cell reactions (5) and (6) were calculated from the measured EMF values as a function of temperature according to Equation (7). The determined Gibbs energies of reactions (5) and (6) are formulated as Equations (8) and (9), respectively.

\[
\Delta_{f(5)}G^\circ/(\text{kJ·mol}^{-1}) = -(3.39 \pm 0.1) - (22.09 \pm 0.5) \cdot 10^{-3} \cdot T/K, \quad (308 < T/K < 367) \tag{8}
\]

\[
\Delta_{f(6)}G^\circ/(\text{kJ·mol}^{-1}) = (3.79 \pm 0.1) - (41.25 \pm 1) \cdot 10^{-3} \cdot T/K, \quad (382 < T/K < 402) \tag{9}
\]

The calculated Gibbs energy in Equation (9) is per mole of the actual formula \((\text{Ag}_{1.01}\text{Cu}_{0.99})\text{S}\) (i.e., \((\text{Ag},\text{Cu})\text{S}\) in reaction (6)).

By combining \(\Delta_{f(5)}G^\circ\) values of reactions (5), i.e., Equation (8), with the molar Gibbs energies of the pure substances obtained from [41], standard Gibbs energies of formation of \(\text{Ag}_{1.2}\text{Cu}_{0.8}\text{S}\) were determined to be:

\[
\Delta_f G^\circ/(\text{kJ·mol}^{-1}) = -(50.2 \pm 1) - (19.1 \pm 0.4) \cdot 10^{-3} \cdot T/K, \quad (308 < T/K < 367) \tag{10}
\]

The Gibbs energies of formation of \(\text{Ag}_{1.2}\text{Cu}_{0.8}\text{S}\) determined in this work are in fair agreement with those experimentally determined values of Schmidt and Sagua [34] for the similar temperature range. We have also calculated the Gibbs energies of formation of \(\text{Ag}_{1.2}\text{Cu}_{0.8}\text{S}\) by applying the Craig and Barton [42] approximation method developed for estimating the Gibbs energies of sulfosalts from simple sulfides, assuming ideal mixing of simple sulfides to form sulfosalts of intermediate composition. To estimate \(\Delta_{\text{mix}}G^\circ = \Delta_{\text{mix}}H^\circ - \Delta_{\text{mix}}S^\circ \cdot T\), they assumed zero enthalpy of mixing (\(\Delta_{\text{mix}}H^\circ = 0\)). Their proposed formula is:

\[
\Delta_f G^\circ_{\text{sulfosalt}}/(\text{kJ·mol}^{-1}) = \Sigma x_i(\Delta_f G^\circ_{\text{sulfide}}) - (5.02 \pm 3.35) \cdot (R \cdot T \cdot \Sigma x_i \ln x_i), \tag{11}
\]

where \( x_i \) is number of moles of the component sulfide.

In the calculation of the Gibbs energies of formation of \(\text{Ag}_{1.2}\text{Cu}_{0.8}\text{S}\), we used the Gibbs energies for \(\text{Cu}_2\text{S}\) and \(\text{Ag}_2\text{S}\) provided in the handbook of Barin [41]. The largest variation of the standard thermodynamic quantities between the experimentally determined and calculated values in this work and the literature value is observed for entropy. A comparative summary of the standard Gibbs energy, enthalpy and entropy values is presented in Table 3.

\(^1\) Authors reported a 1% error for the determined quantities. \(^2\) Data for the simple sulfides in a reaction \(\text{Ag}_2\text{S} + \text{Cu}_2\text{S} = \text{Ag}_{1.2}\text{Cu}_{0.8}\text{S}\) were adapted from [41].

The Gibbs energy data derived in this study can be utilized in the phase diagram modeling of the Ag-Cu-S system, including the Ag\(_2\)S-Cu\(_2\)S system presented in the following section. These thermochemical data can also be extrapolated to different temperature ranges and used to determine the energetics of processes, such as oxidation reactions in the pyrometallurgical processes.

4.3. Results of Thermodynamic Calculations for Optimization

The phase diagram of the Ag\(_2\)S-Cu\(_2\)S system has been optimized using the FactSage software package. The optimization includes both the literature data and the DSC and EMF measurement results in this work. Figure 9 depicts the optimized phase diagram at 1 atm,
together with superimposed literature data and experimental values determined in this work. The low temperature range consists of fifteen stable solid phase regions. To reveal the narrow and complex phase regions, calculations were made between 273 and 430 K (Figure 10).

![Figure 9](image1.png)

**Figure 9.** Optimized phase diagram of the Ag$_2$S-Cu$_2$S system with super imposed literature data [4,6,18,29] and the experimental data determined in this work.

![Figure 10](image2.png)

**Figure 10.** Magnified portions of the optimized phase diagram in the temperature range 273–430 K.

In general, the literature and experimental data for the liquidus and solidus boundaries are precise and consistent with the thermodynamic modeling. The literature data
in the lower temperatures, particularly in the Ag$_2$S-rich part, of the phase diagram are scarcer and scattered. A summary of the experimentally determined and optimized thermodynamic properties in this work is presented in Table 4. The difference between the optimized and experimentally determined temperatures for the transition from AgCuS to (Ag,Cu)$_2$S(HCP) is about 12 K. This difference could be due to the saturation of the phases with different phases, saturation with Ag$_{1.2}$Cu$_{0.8}$S in the modeling and with CuS in the EMF experiment. In the case of the transition from Ag$_{1.2}$Cu$_{0.8}$S to Ag$_{1.55}$Cu$_{0.45}$S in the presence of (Ag,Cu)$_2$S(HCP), in both cases, the temperature difference is only about 4 K, hence, in good agreement.

$^1$The ratio of Ag/Cu = 1.01/0.99. $^2$The ratio of Ag/Cu = 1.09/0.91.

Compared to the phase diagram proposed by Chang et al. [20] in the late 1970s, in the higher temperature range, our model presents lower solidus and liquidus boundaries, for most parts of the compositional ranges. However, our optimized direct melting temperatures for the (Ag,Cu)$_2$S solid solutions is in good agreement with the proposed phase diagram of Chang et al. [20]. In the lower temperature range, the biggest difference is in the phase boundary of the phase region where Ag$_{1.2}$Cu$_{0.8}$S and AgCuS are in equilibrium. There is also a shift for the stromeyerite solubility limit narrow region to the Cu$_2$S-richer region. Compared to the phase diagram of Chang et al. [20], the (Ag,Cu)$_2$S(BCC) + (Cu,Ag)$_2$S(FCC) phase equilibrium in the new phase diagram is narrower and lower on the temperature scale. The solubility limit of Ag$_2$S in the βCu$_2$S phase (denoted as S1) is also observed to be more than double in the new model compared to the phase diagram proposed by Chang et al. [20].

5. Conclusions

Thermal stabilities of selected ternary phases in the Ag$_2$S-richer part of the Ag-Cu sulfide system have been studied with the DSC-TGA and EMF techniques. The ternary compounds Ag$_{1.2}$Cu$_{0.8}$S and AgCuS were equilibrated through high-temperature reaction of the pure Cu$_2$S and Ag$_2$S under vacuum condition. The samples were characterized and then thermally analyzed with the DSC-TGA and EMF techniques under different conditions. From the obtained measurement results, thermodynamic properties of the equilibrium phases have been determined. The determined phase transition temperatures were compared with the available literature values. New data for enthalpy of fusion of the Ag-richer solid solution (Ag,Cu)$_2$S have been determined. From the EMF measurements, we derived the phase transformation AgCuS ⇌ (Ag,Cu)$_2$S(HCP) in the presence of CuS to be 375 ± 1 K and standard Gibbs energies of formation of Ag$_{1.2}$Cu$_{0.8}$S below 375 K to be $\Delta G^\circ / (kJ \cdot mol^{-1}) = -(50.2 \pm 1) - (19.1 \pm 0.4) \cdot 10^{-3} \cdot T/K$. These phase transition properties determined through the two techniques can help to define user limit temperature range for devices incorporating the Ag-Cu-S-ternary phases as functional materials, and the Gibbs energy data can be utilized to determine the energetics of processes such as oxidation reactions in the pyrometallurgical processes.

The experimental results compiled in this work and the critically reviewed literature data incorporating recently published works were combined together with the pure substance database of FactSage version 7.1 to model the latest phase diagram of the Ag$_2$S-Cu$_2$S system. The major differences between the only available phase diagram in the literature,
modeled in the late 1970s, and in this work are on the solidus and liquidus temperatures and the phase stability regions where Ag\(_{1.2}\)Cu\(_{0.8}\)S and AgCuS are in equilibrium.
